80 The Postanesthesia Care Unit

SHERI M. BERG and MATTHIAS R. BRAEHLER

KEY POINTS

- Emergence from general anesthesia and surgery may be accompanied by a number of physiologic disturbances that affect multiple organ systems. Most common are postoperative nausea and vomiting (PONV), hypoxia, hypothermia and shivering, and cardiovascular instability.
- In a prospective study of more than 18,000 consecutive admissions to the postanesthesia care unit (PACU), the complication rate was found to be as high as 24%. Nausea and vomiting (9.8%), the need for upper airway support (6.8%), and hypotension (2.7%) were the most common problems.
- The most frequent cause of airway obstruction in the immediate postoperative period is the loss of pharyngeal muscle tone in a sedated or obtunded patient. The persistent effects of inhaled and intravenous anesthetics, neuromuscular blocking drugs, and opioids all contribute to the loss of pharyngeal tone in the PACU patient.
- Pharyngeal function is not normalized until an adductor pollicis train-of-four (TOF) ratio is greater than 0.90.
- The ability to strongly oppose the incisor teeth against a tongue depressor is a reliable indicator of pharyngeal muscle tone. This maneuver correlates with an average TOF ratio of 0.85 as opposed to 0.60 for the sustained head lift.
- An estimated 8% to 10% of patients who undergo abdominal surgery subsequently require intubation and mechanical ventilation in the PACU. Respiratory failure in the immediate postoperative period is often due to transient and rapidly reversible conditions such as splinting from pain, diaphragmatic dysfunction, muscular weakness, and pharmacologically depressed respiratory drive.
- Although a combination of leads II and V5 will reflect 80% of the ischemic events detected on a 12-lead ECG, visual interpretation of the cardiac monitor is often inaccurate. Because of human error, the American College of Cardiology guidelines recommend that computerized ST-segment analysis be used (if available) to monitor high-risk patients in the immediate postoperative period.
- In one study, urinary retention was defined as bladder volume greater than 600 mL in conjunction with inability to void within 30 minutes and the incidence of postoperative urinary retention in the PACU was 16%. The most significant predictive factors were age older than 50 years, intraoperative fluid greater than 750 mL, and bladder volume on entry to PACU greater than 270 mL.
- Perioperative attention to adequate hydration is indicated in any patient who has received an intravenous contrast agent. Aggressive hydration with a balanced crystalloid solution provides the single most effective protection against contrast nephropathy.
- Rhabdomyolysis has been reported to occur in 22.7% of 66 consecutive patients undergoing laparoscopic bariatric surgery. Risk factors include increased body mass index (BMI) and duration of operation.
- The incidence of postoperative shivering may be as high as 66% after general anesthesia. Identified risk factors include young age, endoprosthetic surgery, and core hypothermia.
- Multiple studies across different surgical specialties in elective and emergency cases have shown that postoperative delirium is associated with worse surgical outcomes, increased hospital length of stay, functional decline, higher rates of institutionalization, higher mortality, and higher cost and resource utilization.
- PACU Standards of Care require that a physician accept responsibility for the discharge of patients from the unit (Standard V). This is the case even when the decision to discharge the patient is made at the bedside by the PACU nurse in accordance with hospital-sanctioned discharge criteria or scoring systems.

The postanesthesia care unit (PACU) is designed and staffed to monitor and care for patients who are recovering from the immediate physiologic effects of anesthesia and surgery. PACU care spans the transition from one-on-one monitoring in the operating room to the less acute monitoring on the hospital ward or, in some cases, independent function of the patient at home. To serve this unique transition period, the PACU is equipped to resuscitate unstable patients while providing a tranquil environment for the "recovery" and comfort of stable patients. Its location in close proximity to the operating rooms facilitates rapid access to anesthesiologists for consultation and assistance.

Admission to the Postanesthesia Care Unit

The PACU is staffed by specially trained nurses skilled in the prompt recognition of postoperative complications. On arrival to the PACU, the anesthesiologist provides the PACU nurse with pertinent details of the patient's history, medical condition, anesthesia, and surgery. Particular attention is directed toward monitoring oxygenation (pulse oximetry), ventilation (breathing frequency, airway patency, capnography), and circulation (systemic blood pressure, heart rate, electrocardiogram [ECG]). Vital signs are recorded as often as necessary but at least every 15 minutes while the patient is in the unit. Vital signs and other pertinent information are recorded as part of the patient's medical record. Specific requirements and recommendations for patient monitoring and therapeutic intervention can be found in the Practice Standards and Guidelines drafted by the American Society of Anesthesiologists.

The Standards for Postanesthesia Care

Practice Standards delineate the required obligation of minimal care in the clinical setting. As such, they serve as a threshold that can be exceeded when indicated by the clinical judgment of the practitioner. The Standards for Postanesthesia Care are updated on a regular basis to keep up with changing practice parameters and technologic advances. The most recent revision published in 2009 is summarized here[1]:

I. All patients who have received general anesthesia, regional anesthesia, or monitored anesthesia care shall receive appropriate postanesthesia management.
II. A patient transported to the PACU shall be accompanied by a member of the anesthesia care team who is knowledgeable about the patient's condition. The patient shall be continually evaluated and treated during transport with monitoring and support appropriate to the patient's condition.
III. Upon arrival in the PACU, the patient shall be reevaluated and a verbal report provided to the responsible PACU nurse by the member of the anesthesia care team who accompanies the patient.
IV. The patient's condition shall be evaluated continually in the PACU. The patient shall be observed and monitored by methods appropriate to the patient's medical condition. Particular attention should be given to monitoring oxygenation, ventilation, circulation, level of consciousness, and temperature. During recovery from all anesthetics, a quantitative method of assessing oxygenation such as pulse oximetry shall be employed in the initial phase of recovery.*
V. A physician is responsible for the discharge of the patient from the PACU.

Unlike Practice Standards, Practice Guidelines are not requirements. They are recommendations designed to assist the healthcare provider in clinical decision making. The ASA Practice Guidelines for Post Anesthetic Care are the result of a multiple-step process that incorporates input from three groups: (1) an ASA-appointed task force consisting of private practice and academic anesthesiologists and epidemiologists, (2) PACU consultants, and (3) ASA members at large. The guidelines are based upon literature review, expert opinion, open forum commentary, and clinical feasibility. They recommend the appropriate assessment, monitoring, and treatment of the major organ system functions during recovery from anesthesia and surgery (Box 80.1).[2]

BOX 80.1 Summary of Recommendations for Patient Assessment and Monitoring in the Postanesthesia Care Unit

Respiratory

Assessment of airway patency, respiratory rate, and oxygen saturation should be periodically performed. Particular attention should be given to monitoring oxygenation and ventilation.

Cardiovascular

Heart rate and blood pressure should be routinely monitored. Electrocardiographic monitors should be immediately available.

Neuromuscular

Assessment of neuromuscular function should be performed for all patients who received nondepolarizing neuromuscular blocking drugs or who have medical conditions associated with neuromuscular dysfunction (also see Chapter 43).

Mental Status

Mental status should be periodically assessed.

Temperature

Patient temperature should be periodically assessed.

Pain

Pain should be periodically assessed.

Nausea and Vomiting

Periodic assessment of postoperative nausea and vomiting should be routinely performed.

Hydration

Postoperative hydration should be assessed and managed accordingly. Certain procedures may involve significant blood loss and require additional intravenous fluids management.

Urine

Assessment of urine output and of urinary voiding should be performed on a case-by-case basis for selected patients or selected procedures.

Drainage and Bleeding

Assessment of drainage and bleeding should be performed periodically as needed.

From Apfelbaum JL, Silverstein JH, Chung FF, et al. Practice guidelines for postanesthetic care: an updated report by the American Society of Anesthesiologists Task Force on Postanesthetic Care. *Anesthesiology*. 2013;118:291–307.

---

*Under extenuating circumstances, the responsible anesthesiologist may waive the requirements marked with an asterisk (*): it is recommended that when this is done, it should be stated (including the reasons) in a note in the patient's medical record.

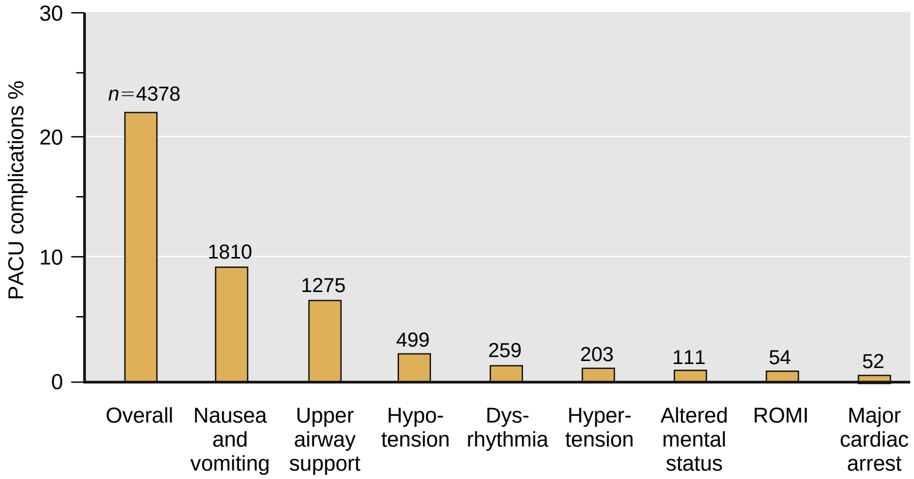

Fig. 80.1 The overall complication rate in 18,473 consecutive patients entering a postanesthesia care unit *(PACU)* was 23.7%. Nausea and vomiting, the need for upper airway support, and hypotension were the most frequent individual complications. (From Hines HR, Barash PG, Watrous G, et al. Complications occurring in the postanesthesia care unit: a survey. *Anesth Analg*. 1992;74:503–509, with permission.)

Early Postoperative Physiologic Changes

Emergence from general anesthesia and surgery may be accompanied by a number of physiologic disturbances that effect multiple organ systems. Most common are postoperative nausea and vomiting (PONV), hypoxia, hypothermia and shivering, and cardiovascular instability. In a prospective study of more than 18,000 consecutive admissions to the PACU, the complication rate was found to be as high as 24%. Nausea and vomiting (9.8%), the need for upper airway support (6.8%), and hypotension (2.7%) were the most common (Fig. 80.1).[3]

Over a 4-year period ending in 1989, 7.1% of the 1175 anesthesia-related malpractice claims in the United States were attributed to recovery room incidents.[4] Despite the significant incidence of nausea and vomiting in the PACU, serious adverse outcomes correlate more closely with airway/respiratory and cardiovascular compromise. In 2002, airway/respiratory problems (183, 43%) and cardiovascular events (99, 24%) accounted for the majority of 419 recovery room incidents reported to the Australian Incident Monitoring Study database (Table 80.1).[5] Similar data were obtained from the United States closed claims database in 1989, in which critical respiratory incidents accounted for more than one-half of the recovery room malpractice claims.[4]

TABLE 80.1 Primary Presenting Problem in 419 Recovery Room Incidents Reported to Australian Incident Monitoring Study

Primary Presenting Problem	No. (%)
Cardiovascular	99 (24)
Respiratory	97 (23)
Airway	86 (21)
Drug error	44 (11)
Central nervous system	32 (8)
Equipment	27 (6)
Communication problems	7 (2)
Hypothermia	6 (1)
Regional block problems	4 (1)
Inadequate documentation	4 (1)
Hyperthermia	3 (1)
Trauma	3 (1)
Dental problems	2 (0.5)
Renal	1 (0.2)
Skin	1 (0.2)
Blood transfusion	1 (0.2)
Facility limitations	1 (0.2)
Gastrointestinal problems	1 (0.2)

Transport to the Postanesthesia Care Unit

Upper airway patency and the effectiveness of the patient's respiratory efforts must be monitored when transporting the patient from the operating room to the PACU. Adequate ventilation can be confirmed by watching for the appropriate rise and fall of the chest wall with inspiration, listening for breath sounds, or simply feeling for exhaled breath with the palm of one's hand over the patient's nose and mouth.

With rare exception, patients who undergo general anesthesia should receive supplemental oxygen during their transport to the PACU. In an observational study of 502 patients admitted to the PACU, breathing room air during transport was the single most significant factor to correlate with hypoxemia (SaO_2 <90%) on arrival. Other significant factors included elevated body mass index (BMI), sedation score, and respiratory rate.[6]

Although the majority of otherwise healthy patients undergoing ambulatory surgery can be transported safely breathing room air, the decision to do so must be made on a case-by-case basis. In the ambulatory setting, advanced age (>60 years) and weight (>100 kg) identifies adults who are at increased risk for oxygen desaturation when breathing room air on transport to the PACU.[7] Hypoventilation alone may cause hypoxemia even in healthy patients who undergo minor procedures.

Upper Airway Obstruction

LOSS OF PHARYNGEAL MUSCLE TONE

The most frequent cause of airway obstruction in the immediate postoperative period is the loss of pharyngeal muscle tone in a sedated or obtunded patient. The persistent effects of inhaled and intravenous anesthetics, neuromuscular blocking drugs, and opioids all contribute to the loss of pharyngeal tone in the PACU patient.

In an awake patient, opening of the upper airway is facilitated by the contraction of the pharyngeal muscles at the same time that negative inspiratory pressure is generated by the diaphragm. As a result, the tongue and soft palate are pulled forward, tenting the airway open during inspiration. This pharyngeal muscle activity is depressed during sleep, and the resulting decrease in tone can promote airway obstruction. A vicious cycle then ensues wherein the collapse of compliant pharyngeal tissue during inspiration produces a reflex compensatory increase in respiratory effort and negative inspiratory pressure that promotes further airway obstruction.[8]

The effort to breathe against an obstructed airway is characterized by a paradoxical breathing pattern consisting of retraction of the sternal notch and exaggerated abdominal muscle activity. Collapse of the chest wall and protrusion of the abdomen with inspiratory effort produces a rocking motion that becomes more prominent with increasing airway obstruction. Obstruction secondary to loss of pharyngeal tone can be relieved by simply opening the airway with the “jaw thrust maneuver” or continuous positive airway pressure (CPAP) applied via a facemask (or both). Support of the airway is needed until the patient has adequately recovered from the effects of drugs administered during anesthesia. In selected patients, placement of an oral or nasal airway, laryngeal mask airway, or endotracheal tube may be required.

RESIDUAL NEUROMUSCULAR BLOCKADE

Postoperative residual neuromuscular blockade is unfortunately very common (Box 80.2). The literature reports incidences between 20% and 40%[9] and a recent study even found that 56% of patients had residual neuromuscular blockade upon arrival in the PACU.[10] When evaluating upper airway obstruction in the PACU, the possibility of residual neuromuscular blockade should be considered in any patient who received neuromuscular blocking drugs during anesthesia.[11,12] Residual neuromuscular blockade may not be evident on arrival in the PACU because the diaphragm recovers from neuromuscular blockade before the pharyngeal muscles do. With an endotracheal tube in place, end-tidal carbon dioxide concentrations and tidal volumes may indicate adequate ventilation while the ability to maintain a patent upper airway and clear upper airway secretions remains compromised. The stimulation associated with tracheal extubation, followed by the activity of patient transfer to the gurney and subsequent encouragement to breathe deeply may keep the airway open during transport to the PACU. Only after the patient is calmly resting in the PACU does upper airway obstruction become evident. Even patients treated with intermediate- and short-acting neuromuscular blocking drugs may manifest residual paralysis in the PACU despite what was deemed clinically adequate pharmacologic reversal in the operating room.

Measurement of the train-of-four (TOF) ratio is a subjective assessment that is often misleading when done by touch or observation alone. A decline in this ratio may not be appreciated until it reaches a value less than 0.4 to 0.5, whereas significant signs and symptoms of clinical weakness persist to a ratio of 0.7.[13] Pharyngeal function is not restored to normal until an adductor pollicis TOF ratio is greater than 0.9.[14]

In the anesthetized patient, a quantitative TOF measurement showing a TOF ratio ≥0.9 is the most reliable

BOX 80.2 Factors Contributing to Prolonged Nondepolarizing Neuromuscular Blockade

Drugs

- Inhaled anesthetic drugs
- Local anesthetics (lidocaine)
- Cardiac antiarrhythmics (procainamide)
- Antibiotics (polymyxins, aminoglycosides, lincosamines [clindamycin], metronidazole [Flagyl], tetracyclines)
- Corticosteroid agents
- Calcium channel blockers
- Dantrolene

Metabolic and Physiologic States

- Hypermagnesemia
- Hypocalcemia
- Hypothermia
- Respiratory acidosis
- Hepatic or renal failure
- Myasthenia syndromes
- Excessive dose of succinylcholine
- Reduced plasma cholinesterase activity
  - Decreased levels
    - Extremes of age (newborn, old age)
    - Disease states (hepatic disease, uremia, malnutrition, plasmapheresis)
    - Hormonal changes
    - Pregnancy
    - Contraceptives
    - Glucocorticoids
  - Inhibited activity
    - Irreversible (echothiophate)
    - Reversible (edrophonium, neostigmine, pyridostigmine)
- Genetic variant (atypical plasma cholinesterase)

indicator of adequate reversal of drug-induced neuromuscular blockade.[13,15] Qualitative TOF measurement and 5-second sustained tetanus at 50 Hz are insensitive and will not allow detection of fade above an average TOF ratio of 0.31 ± 0.15; 5-second sustained tetanus at 100 Hz is unreliable.[16] In an awake patient, clinical assessment of reversal of neuromuscular blockade is preferred to the application of painful TOF or tetanic stimulation. Clinical evaluation includes grip strength, tongue protrusion, the ability to lift the legs off the bed, and the ability to lift the head off the bed for a full 5 seconds. Of these maneuvers, the 5-second sustained head lift has been considered to be the standard, reflecting not only generalized motor strength but, more importantly, the patient's ability to maintain and protect the airway. However, studies have shown that the 5-second head lift is remarkably insensitive and should not routinely be used to assess recovery from neuromuscular blockade. The ability to strongly oppose the incisor teeth against a tongue depressor is a more reliable indicator of pharyngeal muscle tone. This maneuver correlates with an average TOF ratio of 0.85 as opposed to 0.60 for the sustained head lift.[13] In a year-long study of 7459 PACU patients who had received general anesthesia, Murphy et al. reported critical respiratory events (CREs) in 61 of them. These events occurred within the first 15 minutes of PACU admission, at which time a TOF ratio was measured. When compared with matched controls, these patients had a significantly lower TOF ratio (0.62 [+0.20]) compared to controls 0.98 [+0.07]).[17] In a recent study, Bulka and associates were able to demonstrate that patients who had received neuromuscular blocking drugs, but did not receive reversal agents, had a 2.26 times higher risk of developing postoperative pneumonia compared to those who did receive reversal agents.[18]

When a PACU patient demonstrates signs and/or symptoms of muscular weakness in the form of respiratory distress and/or agitation, one must suspect that there could be a residual neuromuscular blockade and prompt review of possible etiologic factors is indicated (see Box 80.2). Common factors include respiratory acidosis and hypothermia, alone or in combination. Upper airway obstruction as a result of the residual depressant effects of volatile anesthetics or opioids (or both) may result in progressive respiratory acidosis after the patient is admitted to the PACU and external stimulation is minimized. Simple measures such as warming the patient, airway support, and correction of electrolyte abnormalities can facilitate recovery from neuromuscular blockade. The approval of sugammadex in the United States by the FDA in December 2015 may have a major impact on residual paralysis in patients who were paralyzed with aminosteroid neuromuscular blocking drugs (sugammadex does not work with benzylisoquinolinium neuromuscular blocking drugs). While reversal with neostigmine requires a baseline twitch response, and the duration until the patient has a TOF ratio of ≥0.9 is highly variable, sugammadex can be administered at any depth of neuromuscular blockade and most commonly produces full recovery within several minutes after administration. In a recent study, reversal with sugammadex resulted in a return of TOF ratio to greater than 0.9 within 5 minutes in 85% of patients with no twitches on TOF stimulation.[19] It is anticipated that the increased availability and use of sugammadex, as an alternative to neostigmine, will result in a decreased incidence of residual neuromuscular blockade in the PACU.

LARYNGOSPASM

Laryngospasm refers to a sudden spasm of the vocal cords that completely occludes the laryngeal opening via forceful tonic contractions of the laryngeal muscles and descent of the epiglottis over the laryngeal inlet. It typically occurs in the transitional period when the extubated patient is emerging from general anesthesia yet not fully awake. Although laryngospasm is most likely to occur in the operating room at the time of tracheal extubation, patients who arrive in the PACU asleep after general anesthesia are also at risk for laryngospasm upon awakening, which is often triggered by airway irritants, such as secretions or blood. Treatment of laryngospasm involves removal of the stimulus (suctioning of secretions, blood) and the application of a jaw thrust maneuver with CPAP (up to 40 cm water [H_2O]) is often sufficient stimulation to break the laryngospasm. However, if jaw thrust maneuver and CPAP fail, then immediate skeletal muscle relaxation can be achieved with succinylcholine (0.1-1.0 mg/kg intravenously [IV] or 4 mg/kg intramuscularly [IM]). If these maneuvers fail, one should proceed with a full dose of an induction agent and intubating dose of a muscle relaxant to enable the practitioner to perform an emergent tracheal intubation; attempting to pass a tracheal tube forcibly through a glottis that is closed because of laryngospasm is not acceptable.

EDEMA OR HEMATOMA

Airway edema is a possible surgical complication in patients undergoing prolonged procedures in the prone or Trendelenburg position, procedures involving the airway and neck (including thyroidectomy,[20] carotid endarterectomy,[21] and cervical spine procedures[22]), as well as those in which the patient receives a large volume resuscitation. Although facial and scleral edema is an important physical sign that can alert the clinician to the presence of airway edema, visible external signs may not accompany significant edema of pharyngeal tissue (see also Chapter 44). Patients who have had a difficult intraoperative intubation and/or airway instrumentation may also have increased airway edema from direct injury. If tracheal extubation is to be attempted in these patients in the PACU, then evaluation of airway patency must precede removal of the endotracheal tube. The patient's ability to breathe around the endotracheal tube can be evaluated by suctioning the oral pharynx and deflating the endotracheal tube cuff. With occlusion of the proximal end of the endotracheal tube, the patient is then asked to breathe around the tube. Good air movement suggests that the patient's airway will remain patent after tracheal extubation. An alternative method involves measuring the intrathoracic pressure required to produce a leak around the endotracheal tube with the cuff deflated. This method was originally used to evaluate pediatric patients with croup before extubation.[23-25] When used in patients with general oropharyngeal edema, the safe pressure threshold can be difficult to identify. Lastly, when ventilating patients in the volume control mode, one can measure the exhaled tidal volume before and after cuff deflation. Patients who require reintubation generally have a smaller leak (i.e., less percentage difference between exhaled volume before and after cuff deflation) than those who do not. A difference greater than 15.5% is the advocated cutoff value for extubation of the trachea.[26] The presence of a cuff leak demonstrates the likelihood of successful extubation, not a guarantee, just as a failed cuff leak does not rule out a successful extubation.[27] The cuff leak test does not and should never take the place of sound clinical judgment, as it is neither sensitive nor specific; it may be used as an adjunct to aid in providing another layer of guidance.

In order to facilitate the reduction of airway edema, one may sit the patient upright to ensure adequate venous drainage, and consider administering a diuretic and intravenous dexamethasone (4-8 mg every 6 hours for 24 hours), which may help decrease airway swelling.

External airway compression is most often caused by hematomas following thyroid, parathyroid, or carotid surgical procedures. Patients may complain of pain and/or pressure, dysphagia, and can demonstrate signs of respiratory distress as the pressure from the expanding hematoma within the tissue can disrupt both venous and lymphatic drainage, both of which can further exacerbate airway swelling. Mask ventilation may not be possible in a patient with severe upper airway obstruction resulting from edema or hematoma. In the case of a hematoma, an attempt can be made to decompress the airway by releasing the clips or sutures on the wound and evacuating the hematoma. This maneuver is recommended as a temporizing measure, but it will not effectively decompress the airway if a significant amount of fluid or blood (or both) has infiltrated the tissue planes of the pharyngeal wall. If emergency tracheal intubation is required, then ready access to difficult airway equipment and surgical backup to perform an emergency tracheostomy are crucial, as one should assume increased difficulty secondary to laryngeal and airway edema, possible tracheal deviation, and a compressed tracheal lumen. If the patient is able to move adequate air via spontaneous ventilation, then an awake technique is often preferred as visualization of the cords by direct laryngoscopy may not be possible.

OBSTRUCTIVE SLEEP APNEA

Obstructive sleep apnea (OSA) syndrome is an often overlooked cause of airway obstruction in the PACU, given that most patients are actually not obese and the vast majority of patients are undiagnosed at the time of surgery.[28,29]

It is well known that patients with OSA are at an increased risk of suffering from cardiopulmonary complications as compared to the general population not affected by OSA syndrome. Patients with OSA are particularly prone to airway obstruction and should not be extubated until they are fully awake and following commands.[30,31] Any redundant compliant pharyngeal tissue in these patients not only increases the incidence of airway obstruction, but can also increase the difficulty of intubation by direct laryngoscopy.[32,33] Once in the PACU, a patient with OSA whose trachea has been extubated is exquisitely sensitive to opioids and, when possible, continuous regional anesthesia techniques should be used to provide postoperative analgesia.[34,35] Other opioid-sparing techniques should be utilized, such as scheduled acetaminophen, and use of nonsteroidal antiinflammatory drugs (NSAIDs) when not contraindicated. One may also employ the use of ketamine, dexmedetomidine, and clonidine, all of which can also decrease postoperative opioid requirements. Interestingly, benzodiazepines can have a greater effect on pharyngeal muscle tone than opioids, and the use of benzodiazepines in the perioperative setting can significantly contribute to airway obstruction in the PACU.[8,36]

Another strategy to employ when caring for a patient with OSA is to position them in either an upright (seated, reverse Trendelenburg) or semi-upright position whenever possible, as the supine position is known to worsen OSA.

In addition, the use of goal-directed fluid strategies should be utilized with consideration of lower salt-containing substances, as these patients are more prone to fluid shifts, which can worsen airway edema.

When caring for a patient with OSA, plans should be made preoperatively to provide CPAP in the immediate postoperative period. Patients should be asked to bring their own CPAP machines with them on the day of surgery to enable the equipment to be set up before the patient's arrival in the PACU. Patients who do not routinely use CPAP at home or who do not have their machines with them may require additional attention from the respiratory therapist to ensure proper fit of the CPAP delivery device (mask or nasal airways) and to determine the amount of positive pressure needed to prevent upper airway obstruction.[37,38]

In patients with OSA who are morbidly obese, immediately applying CPAP postextubation in the operating room rather than waiting to apply positive pressure in the PACU may offer additional benefits. In patients undergoing laparoscopic bariatric surgery, Neligan and colleagues compared the application of 10 cm H_2O CPAP immediately postextubation to instituting the same CPAP 30 minutes later in the PACU. When compared with matched controls, patients who received immediate CPAP demonstrated improved spirometric lung function (i.e., functional residual capacity [FRC], peak expiratory flow [PEF], and forced expiratory volume [FEV]) at 1 hour and 24 hours postoperatively.[38]

Two large cohort studies demonstrated that patients with OSA who are not treated with positive airway pressure (PAP) preoperatively are at increased risk for cardiopulmonary complications after general and vascular surgery and that PAP therapy was associated with a reduction in postoperative cardiovascular complications. If the patient can tolerate PAP, and their surgical procedure is not a contraindication to its application, patients with OSA should use a PAP device postoperatively.

Management of Upper Airway Obstruction

An obstructed upper airway requires immediate attention. Efforts to open the airway by noninvasive measures should be attempted before reintubation of the trachea. Jaw thrust with CPAP (5-15 cm H_2O) is often enough to tent the upper airway open in patients with decreased pharyngeal muscle tone. If CPAP is not effective, an oral, nasal, or laryngeal mask airway can be inserted rapidly. After successfully opening the upper airway and ensuring adequate ventilation, the cause of the upper airway obstruction should be identified and treated. In adults the sedating effects of opioids and benzodiazepines can be reversed with persistent stimulation or small, titrated doses of naloxone (0.3-0.5 µg/kg IV) or flumazenil (0.2 mg IV to maximum dose of 1 mg), respectively. Residual effects of neuromuscular blocking drugs can be reversed pharmacologically or by correcting contributing factors such as hypothermia.

Differential Diagnosis of Arterial Hypoxemia in the Postanesthesia Care Unit

Atelectasis and alveolar hypoventilation are the most common causes of transient postoperative arterial hypoxemia in the immediate postoperative period.[39] Clinical correlation should guide the workup of a postoperative patient who remains persistently hypoxic.[40] Review of the patient's history, operative course, and clinical signs and symptoms will direct the workup to rule in possible causes (Box 80.3).

ALVEOLAR HYPOVENTILATION

Review of the alveolar gas equation demonstrates that hypoventilation alone is sufficient to cause arterial hypoxemia in a patient breathing room air (Fig. 80.2). At sea level, a normocapnic patient breathing room air will have an alveolar oxygen pressure (PAO_2) of 100 mm Hg. Thus, a healthy patient without a significant alveolar-arterial gradient will have a PaO_2 near 100 mm Hg. In the same patient, an increase in $PaCO_2$ from 40 to 80 mm Hg (alveolar hypoventilation) results in a PaO_2 of 50 mm Hg. Hence, even a patient with normal lungs will become hypoxic if allowed to significantly hypoventilate while breathing room air.

Normally, minute ventilation increases linearly by approximately 2 L/min for every 1-mm Hg increase in $PaCO_2$. In the immediate postoperative period, the residual effects of inhaled anesthetics, opioids, and sedative-hypnotics can significantly depress this ventilatory response to carbon dioxide. In addition to depressed respiratory drive, the differential diagnosis of postoperative hypoventilation includes generalized weakness due to residual neuromuscular blockade or underlying neuromuscular disease. The presence of restrictive pulmonary conditions, such as preexisting chest wall deformity, postoperative abdominal binding, or abdominal distention, can also contribute to inadequate ventilation.

Arterial hypoxemia secondary to hypercapnia can be reversed by the administration of supplemental oxygen (Fig. 80.3)[41] or by normalizing the patient's $PaCO_2$ by external stimulation of the patient to wakefulness, pharmacologic reversal of opioid or benzodiazepine effect, or controlled mechanical ventilation of the patient's lungs.

BOX 80.3 Factors Contributing to Postoperative Arterial Hypoxemia

- Right-to-left intrapulmonary shunt (atelectasis)
- Mismatching of ventilation to perfusion (decreased functional residual capacity)
- Congestive heart failure
- Pulmonary edema (fluid overload, postobstructive edema)
- Alveolar hypoventilation (residual effects of anesthetics and/or neuromuscular blocking drugs)
- Diffusion hypoxia (unlikely if receiving supplemental oxygen)
- Inhalation of gastric contents (aspiration)
- Pulmonary embolus
- Pneumothorax
- Increased oxygen consumption (shivering)
- Sepsis
- Transfusion-related lung injury
- Adult respiratory distress syndrome
- Advanced age
- Obesity

$$PAO_2 = FiO_2\,(PB - PH_2O) - \frac{PaCO_2}{RQ}$$

$$PaCO_2 = 40 \text{ mm Hg}$$
$$PAO_2 = 21(760 - 47) - \frac{40}{0.8} = 150 - 50 = 100 \text{ mm Hg}$$

$$PaCO_2 = 80 \text{ mm Hg}$$
$$PAO_2 = 21(760 - 47) - \frac{80}{0.8} = 150 - 100 = 50 \text{ mm Hg}$$

PAO_2 = alveolar oxygen pressure
$PaCO_2$ = partial pressure of CO_2 in arterial blood
FiO_2 = fraction of inspired oxygen
PB = barometric pressure
PH_2O = vapor pressure of water
RQ = respiratory quotient

Fig. 80.2 Hypoventilation as a cause of arterial hypoxemia. (From Nicholau D. Postanesthesia recovery. In: Miller RD, Pardo MC Jr, eds. *Basics of Anesthesia.* 7th ed. Philadelphia: Elsevier; 2018.)

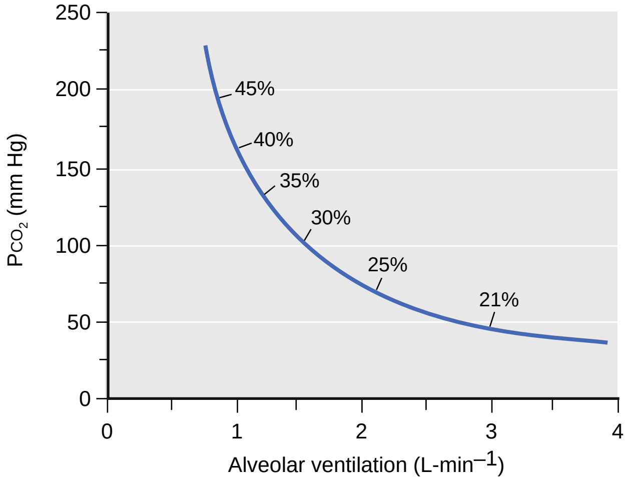

Fig. 80.3 Alveolar partial pressure of carbon dioxide (PCO_2) as a function of alveolar ventilation at rest. The percentages indicate the inspired oxygen concentration required to restore alveolar partial pressure of oxygen (PO_2) to normal. (Adapted from Nunn JF. *Nunn's Applied Respiratory Physiology.* 6th ed. Philadelphia: Butterworth-Heinemann; 2005, with permission.)

DECREASED ALVEOLAR OXYGEN PRESSURE

Diffusion hypoxia refers to the rapid diffusion of nitrous oxide into alveoli at the end of a nitrous oxide anesthetic. Nitrous oxide dilutes the alveolar gas and produces a transient decrease in Pao_2 and $Paco_2$. In a patient breathing room air, the resulting decrease in Pao_2 can produce arterial hypoxemia while decreased $Paco_2$ can depress the respiratory drive. In the absence of supplemental oxygen administration, diffusion hypoxia can persist for 5 to 10 minutes after discontinuation of a nitrous oxide anesthetic; therefore, it may contribute to arterial hypoxemia in the initial moments in the PACU.

VENTILATION-PERFUSION MISMATCH AND SHUNT

Hypoxic pulmonary vasoconstriction refers to the attempt of normal lungs to optimally match ventilation and perfusion. This response constricts vessels in poorly ventilated regions of the lung and directs pulmonary blood flow to well-ventilated alveoli. In the PACU, the residual effects of inhaled anesthetics and vasodilators such as nitroprusside and dobutamine used to treat systemic hypertension or improve hemodynamics will blunt hypoxic pulmonary vasoconstriction and contribute to arterial hypoxemia.

Unlike a mismatch, a true shunt will not respond to supplemental oxygen. Causes of postoperative pulmonary shunt include atelectasis, pulmonary edema, gastric aspiration, pulmonary emboli, and pneumonia. Of these, atelectasis is probably the most common cause of pulmonary shunting in the immediate postoperative period. Mobilization of the patient to the sitting position, incentive spirometry, and PAP by facemask can be effective in treating atelectasis.

INCREASED VENOUS ADMIXTURE

Increased venous admixture typically refers to low cardiac output states. It is due to the mixing of desaturated venous blood with oxygenated arterial blood. Normally, only 2% to 5% of cardiac output is shunted through the lungs, and this shunted blood with a normal mixed venous saturation has a minimal effect on Pao_2. In low cardiac output states, blood returns to the heart severely desaturated. Additionally, the shunt fraction increases significantly in conditions that impede alveolar oxygenation, such as pulmonary edema and atelectasis. Under these conditions, mixing of desaturated shunted blood with saturated arterialized blood decreases Pao_2.

DECREASED DIFFUSION CAPACITY

A decreased diffusion capacity may reflect the presence of underlying lung disease such as emphysema, interstitial lung disease, pulmonary fibrosis, or primary pulmonary hypertension. In this regard, the differential diagnosis of arterial hypoxemia in the PACU must include the contribution of any preexisting pulmonary condition.

Finally, keep in mind that inadequate oxygen delivery may result from an unrecognized disconnection of the oxygen source or empty oxygen tank.

Pulmonary Edema

Pulmonary edema in the immediate postoperative period is often cardiogenic in nature, secondary to intravascular volume overload or congestive heart failure. Other causes of noncardiogenic pulmonary edema, namely postobstructive pulmonary edema (secondary to airway obstruction), sepsis, or transfusion (transfusion-related acute lung injury [TRALI]), may occur less frequently, but they must not be overlooked as a potential cause of pulmonary edema in the postoperative period.

POSTOBSTRUCTIVE PULMONARY EDEMA

Postobstructive pulmonary edema (also referred to as negative pressure pulmonary edema, NPPE) is a rare, but significant consequence of laryngospasm and other upper airway obstruction that may follow tracheal extubation at the conclusion of anesthesia and surgery. Laryngospasm is likely the most common cause of postobstructive pulmonary edema in the PACU, but postobstructive pulmonary edema may result from any condition that occludes the upper airway.[42-45] The etiology of NPPE is multifactorial, but is clearly correlated with the generation of exaggerated negative intrathoracic pressure attributable to forced inspiration against a closed glottis. The resulting negative intrathoracic pressure augments blood flow to the right side of the heart, which in turn dilates and increases hydrostatic pressure gradient across the pulmonary vascular bed, promoting the movement of fluid into the interstitial and alveolar spaces from the pulmonary capillaries. Negative inspiratory pressure will also increase left ventricular afterload, thus decreasing the ejection fraction, which heightens left ventricular end diastolic pressure, left atrial pressure, and pulmonary venous pressure. This chain of events further escalates the development of pulmonary edema via increase of pulmonary hydrostatic pressures. Patients who are muscularly healthy are at increased risk of postobstructive pulmonary edema secondary to their ability to generate significant inspiratory force.

The resulting arterial hypoxemia develops relatively quickly (usually observed within 90 minutes of the upper airway obstruction), and is accompanied by dyspnea, pink frothy sputum, and bilateral fluffy infiltrates on the chest radiograph. Treatment is generally supportive and includes supplemental oxygen, diuresis, and, in severe cases, initiation of positive-pressure ventilation. The general consensus of postoperative monitoring in these patients ranges anywhere from 2 to 12 hours. Resolution of NPPE typically occurs within 12 to 48 hours when recognized and treated immediately; however, if diagnosis and resulting therapy is delayed, mortality rates can reach 40%. Although it is quite uncommon, pulmonary hemorrhage and hemoptysis have been observed.

TRANSFUSION-RELATED ACUTE LUNG INJURY

The differential diagnosis of pulmonary edema in the PACU should include transfusion-related lung injury in any patient who intraoperatively received blood products.[46-48] Transfusion-related lung injury is typically exhibited within 2 to 4 hours after the transfusion of plasma-containing blood products, including packed red blood cells, whole blood, fresh frozen plasma, or platelets. TRALI occurs when recipient neutrophils become activated by constituents of the donor blood products. These neutrophils then release inflammatory mediators which initiate the cascade of pulmonary edema and resulting lung injury via increasing the permeability of the pulmonary vasculature. Given that presenting symptoms (sudden onset of hypoxemic respiratory failure) can appear up to 6 hours after the conclusion of the transfusion, the syndrome may develop during the patient's stay in the PACU. The resulting noncardiogenic pulmonary edema is often associated with fever, pulmonary infiltrates on chest radiograph (without signs of left heart failure), cyanosis, and systemic hypotension. If a complete blood cell count is obtained with the onset of symptoms, then documenting an acute drop in the white blood cell count (leukopenia) is possible, reflecting the sequestration of granulocytes within the lung and exudative fluid.[49,50]

Treatment is supportive and includes supplemental oxygen and diuresis. It is estimated that up to 80% of patients will recover within 48 to 96 hours. Mechanical ventilation may be needed to support hypoxemia and respiratory failure. Vasopressors may be required to treat refractory hypotension.[51,52]

In past years, the lack of specific diagnostic criteria has resulted in the underdiagnosing and underreporting of this syndrome. Recently, a group of transfusion experts in the American-European Consensus Conference developed and implemented diagnostic criteria that have raised the awareness of the syndrome (Box 80.4).[51,53-56]

BOX 80.4 Criteria for the Diagnosis of Transfusion-Related Acute Lung Injury: the American-European Consensus Conference Recommendations

1. Acute lung injury evidenced by:
    a. Acute onset of signs and symptoms
    b. Hypoxemia:
        i. PaO_2/FiO_2 <300, or
        ii. Room air SpO_2 <90%, or
        iii. Other clinical evidence of hypoxemia
    c. Bilateral infiltrates on chest radiography without cardiomegaly
    d. No clinical evidence of left atrial hypertension
2. No preexisting acute lung injury before transfusion
3. Onset of lung dysfunction within 6 h of transfusion
4. No temporal association of onset to alternative causes of acute lung injury

Modified from Swanson K, Dwyre DM, Krochmal J, et al. Transfusion-related acute lung injury (TRALI): current clinical and pathophysiologic considerations. *Lung*. 2006;184:177–185.

TRANSFUSION-ASSOCIATED CIRCULATORY OVERLOAD (TACO)

TACO may be difficult to distinguish from TRALI, however TACO should be highly considered in patients who have diminished cardiac function at baseline, renal insufficiency, and in surgical procedures where there is both rapid and large-volume fluid and blood product administration.[57] Patients with TACO are essentially unable to manage the rate and/or volume of product received secondary to their underlying comorbidities, and tend to develop symptoms of respiratory distress, hypoxemia, and signs of left and/or right heart failure within 2 to 6 hours of the transfusion. TACO is commonly associated with physical manifestations of fluid overload and these patients frequently are hypertensive during the onset of dyspnea. The chest radiograph may demonstrate findings of preexisting cardiac disease and a possible cardiogenic component, such as cardiomegaly and pleural effusions. Elevated levels of BNP are suggestive of TACO. TACO and TRALI may indeed coexist. Treatment is mainly supportive and should focus on treatment of supplemental oxygen for hypoxemia and diuresis for acute volume overload. Positive pressure ventilation can be employed as well.

Monitoring and Treatment of Hypoxemia

OXYGEN SUPPLEMENTATION

In the era of cost containment, it has been suggested that the routine delivery of supplemental oxygen to all patients recovering from general anesthesia is a costly and unnecessary practice.[58] The argument against the use of routine oxygen supplementation relies on the fact that continuous pulse oximetry, now a PACU standard, readily identifies those patients who will require oxygen therapy.[59] Supporting this argument is the observation that after general anesthesia a majority of patients do not become hypoxic (63% at threshold of Sao_2 <90%, and 83% at threshold of Sao_2 <94%) when breathing room air in the PACU.[59] Although the authors of this observational study predict that the elimination of routine oxygen supplementation in the PACU would result in significant cost savings, others assert that the economic benefit of limited oxygen therapy is likely to be offset by the cost of complications.[60,61]

Although the practice of providing prophylactic oxygen therapy to all patients after general anesthesia is controversial, most would argue that the benefits outweigh the risks. Even with oxygen supplementation, a significant percentage of patients will become hypoxic at some point during their PACU stay.[62,63] Russell and associates studied 100 patients who were transferred to the PACU breathing room air before receiving at least 40% oxygen by aerosol face tent in the unit.[62] All patients had an Sao_2 greater than 97% before the 2-minute transport to the PACU. Fifteen percent of patients experienced transient desaturation on arrival in the PACU (<92% saturation for >30 seconds). This immediate desaturation correlated positively with patient age, body weight, ASA classification, general anesthesia, and increased volume of intravenous fluid greater than 1500 mL. An even larger percentage of patients (25%) desaturated 30 to 50 minutes later in their PACU stay despite prophylactic oxygen administration. These later desaturations were more severe (71%-91%) and lasted longer (5.8 ± 12.6 minutes) than those that occurred on admission. Additional correlating factors included duration of anesthesia and female gender.

The safe practice of postanesthesia care without oxygen supplementation requires ideal conditions at all times; that is, functioning oxygen delivery apparatus at every bedside as well as sufficient manpower for observation and immediate intervention. Gravenstein argues that this degree of vigilance is likely unrealistic and the risk of adverse outcome to even a small number of patients is unwarranted.[64]

LIMITATIONS OF PULSE OXIMETRY

The ASA Standards for Postanesthesia Care require that patients be observed and monitored with "particular attention given to" both oxygenation and ventilation. The pulse oximeter is a standard monitor in the PACU for the detection of hypoxemia, but it does not reflect the adequacy of ventilation.[65] Although several studies have demonstrated oximetry's limited ability to detect hypoventilation in patients breathing room air,[66,67] they confirm that it does not reliably detect hypoventilation in patients breathing oxygen.[67] When monitoring ventilation in the PACU, pulse oximetry is not a substitute for close observation by trained personnel.

Oxygen Delivery Systems

SUPPLEMENTAL OXYGEN

The degree of hypoxemia, the surgical procedure, and patient compliance determine the oxygen delivery system of choice in the PACU. Regardless of the delivery system, oxygen should be humidified in order to prevent the subsequent dehydration of the nasal and/or oral mucosa. Patients who have just undergone head and neck surgery may not be candidates for facemask oxygen because of the risk of pressure necrosis on incision sites and microvascular muscle flaps, whereas nasal packing prohibits the use of nasal cannulas in others. Face tent oxygen or blow-by setups are viable alternatives in cases in which tight-fitting masks and straps are contraindicated. In an elderly patient, or one who is at an increased risk of delirium, nasal cannula may be selected over a facemask, as long as their oxygenation saturation levels are adequate.

Simple facemasks are generally used in the postoperative setting in patients who are breathing spontaneously yet require a higher oxygen flow rate and/or concentration in order for them to maintain their oxygenation saturation. The practitioner should ensure the proper size, as the mask should fit comfortably over the patient's nose and mouth. Oxygen flow rates should be at least 5 L/min in order to preclude rebreathing of CO_2. Nonrebreather masks have traditionally been known to deliver the highest concentration (up to 95%) in spontaneously breathing patients.

The delivery of oxygen through a traditional nasal cannula with bubble humidifier is usually limited to a maximum flow of 6 L/min to minimize the discomfort and complications that result from inadequate humidification. As a general rule, each liter per minute of oxygen flow through nasal cannula increases the FiO_2 by 0.04, with 6 L/min delivering an FiO_2 of approximately 0.44.

Until recently, maximum oxygen delivery to extubated patients required delivery by facemask through a nonrebreather system or high-flow nebulizer. These systems can be inefficient, however, because of inadequate mask fit and/or high-minute ventilation requirements that result in significant entrainment of room air. The newer high-flow nasal cannula (HFNC) devices can comfortably deliver oxygen at 40 L/min, 37°C, and 99.9% relative humidity.[68] The delivery of high-flow oxygen directly to the nasopharynx produces an FiO_2 equal to that delivered by traditional mask devices. HFNC is an appropriate alternative in patients with hypoxemic respiratory failure without hypercapnia. In fact, the Vapotherm system has been shown to deliver a higher FiO_2 than a nonrebreather mask at similar flow ranges (10-40 L/min). Unlike the nonrebreather mask, these devices deliver high-flow oxygen directly to the nasopharynx throughout the respiratory cycle.[69,70] The efficacy of these devices may be enhanced by a CPAP effect resulting from the high gas flow.[71]

In a recent meta-analysis by Zhao et al., it was concluded that HFNC, when compared to conventional oxygen therapy systems, reduced the need for mechanical ventilation[72]; however outcomes were similar when compared to noninvasive ventilation.

CONTINUOUS POSITIVE AIRWAY PRESSURE

An estimated 8% to 10% of patients who undergo abdominal surgery subsequently require intubation and mechanical ventilation in the PACU. As discussed earlier in this chapter, respiratory failure in the immediate postoperative period is often due to transient and rapidly reversible conditions such as splinting from pain, diaphragmatic dysfunction, muscular weakness, and pharmacologically depressed respiratory drive. Readily reversible hypoxemia may be due to hypoventilation, atelectasis, or volume overload. The application of CPAP in this setting can potentially decrease hypoxemia as a result of atelectasis by recruiting alveoli. The resulting increase in functional reserve capacity may also improve pulmonary compliance and decrease the work of breathing.

A large percentage of patients who are obese and undergoing Roux-en-Y gastric bypass surgery have OSA and stand to benefit significantly from postoperative CPAP therapy. Yet surgeons were initially hesitant to embrace this modality for fear that applying positive pressure to the airway would inflate the stomach and proximal intestine and result in anastomotic disruption. In a single-center study of 1067 patients undergoing gastro-jejunostomy bypass and 420 diagnosed with OSA, CPAP did not increase the risk of postoperative anastomotic leaks.[73]

NONINVASIVE POSITIVE-PRESSURE VENTILATION

Even with the application of CPAP in the PACU, a number of patients will require additional ventilatory support. Noninvasive positive-pressure ventilation (NIPPV) has been shown to be an effective alternative to endotracheal intubation in the intensive care unit (ICU) setting. Although the use of NIPPV in both chronic and acute respiratory failure is well established, its application in the PACU is limited.

In the past, the use of NIPPV was avoided in the immediate postoperative period because of the potential for gastric distention, aspiration, and wound dehiscence. These potential complications were especially true in patients who had undergone esophageal or gastric surgery. Careful consideration of both the patient and the surgical factors must guide the decision to use noninvasive modes of ventilation in the PACU. Relative contraindications include hemodynamic instability or life-threatening arrhythmias, altered mental status, high risk of aspiration, inability to use nasal or facial mask (head and neck procedures), and refractory hypoxemia.[74,75]

NIPPV can be delivered by facemask using the pressure support mode of a mechanical ventilator. Alternatively, the use of a biphasic PAP machine allows the delivery of positive pressure by either nasal cannula or facemask. An example protocol for instituting NIPPV in patients with acute respiratory failure is shown in Box 80.5.[76]

NIPPV should be considered postoperatively in patients with OSA, COPD, and cardiogenic pulmonary edema. Utilization of PPV postextubation in the immediate postoperative periods may aid in the prevention of atelectasis as well as ensuing respiratory failure. There have been several studies that investigated the prophylactic use of NIPPV in the bariatric, general, thoracic, and vascular surgical populations. Despite the fact that there is lack of data demonstrating succinct results and large RCTs, NIPPV has shown to be beneficial in distinctive patient populations.[77]

Patients who are able to cooperate and tolerate PPV, as well as those with an intact mental status, moderate hypercarbia and academia ($PaCO_2$ 45-92, pH 7.1-7.35), and physiologic improvement within 2 hours are often associated with higher rates of success with NIPPV. Relative contraindications to PPV include copious secretions, lack of an intact mental status, cardiac or respiratory arrest, and those who are considered to be high aspiration risks or are unable to protect their airway.

BOX 80.5 **Example Protocol for Instituting Noninvasive Positive-Pressure Ventilation in Patients with Acute Respiratory Failure**

1. Choose the appropriate patient, based on the surgical procedure and the patient's risk of aspiration, ability to protect his or her airway, and ability to comply with the mask fit.
2. Position the head of the bed at ≥45-degree angle.
3. Choose the correct size mask and connect mask to ventilator.
4. Explain the modality to the patient and provide reassurance.
5. Set initial ventilatory settings (CPAP, 0 cm H_2O; pressure support, 10 cm H_2O).
6. Gently hold mask on face until the patient is comfortable and synchronous with ventilation.
7. Apply wound care dressing on nasal bridge and other pressure points.
8. Secure mask with head straps.
9. Slowly increase CPAP.
10. Adjust pressure support to achieve adequate tidal volumes and maximal patient comfort.
11. In patients with hypoxia, increase CPAP in increments of 2 to 3 cm H_2O until FiO_2 is ≤0.6.
12. Avoid peak mask pressures >30 cm H_2O.
13. Set ventilator alarms and apnea backup parameters.
14. Ask the patient and nurse to call for needs (e.g., repositioning mask, pain, discomfort) or if complications occur (e.g., respiratory difficulties, abdominal distention, nausea, vomiting).
15. Monitor with oximetry, and adjust ventilator settings after blood gas results.

Hemodynamic Instability

Hemodynamic compromise in the patient in the PACU is exhibited in a number of ways—systemic hypertension, hypotension, tachycardia, or bradycardia—alone or in combination. Hemodynamic instability in the PACU has a negative impact on long-term outcome. Interestingly, postoperative systemic hypertension and tachycardia are associated with an increased risk of unplanned critical care admission and a higher mortality than hypotension and bradycardia.[78]

SYSTEMIC HYPERTENSION

Patients with a history of essential hypertension are at greatest risk for significant systemic hypertension in the PACU, especially if they did not take their morning antihypertensive medications.[79] Additional factors include pain (which is usually associated with tachycardia +/− tachypnea), nausea and vomiting, hypoventilation and associated hypercapnia, hypoxia, emergence excitement, anxiety, agitation, advanced age, urinary retention (secondary to large intraoperative administration of IV fluids), and preexisting renal disease (Box 80.6). One must also not forget the possibility of alcohol withdrawal (which can occur as early as 24 hours after the patient's last alcohol consumption). Drug withdrawal must also be considered as a possibility; this can be secondary to β-blocker withdrawal, or opioid or benzodiazepine withdrawal as well. Recent use/abuse of certain recreational drugs, such as cocaine, methamphetamines, or LSD/PCP can all produce exaggerated sympathetic states and patients under the influence of these will present with tachycardia and hypertension.

The surgical procedures most commonly associated with postoperative hypertension are carotid endarterectomy and intracranial procedures. A significant number of patients, especially those with a known history of hypertension, will require pharmacologic blood pressure control in the PACU.

BOX 80.6 Factors Leading to Postoperative Hypertension

- Preoperative hypertension
- Arterial hypoxemia
- Hypervolemia
- Emergence excitement
- Shivering
- Drug rebound
- Increased intracranial pressure
- Increased sympathetic nervous system activity
  - Hypercapnia
  - Pain
  - Agitation
  - Bowel distention
  - Urinary retention

BOX 80.7 Differential Diagnosis of Hypotension in the Postanesthesia Care Unit

- Intravascular volume depletion
  - Persistent fluid losses
  - Ongoing third-space translocation of fluid
  - Bowel preparation
  - Gastrointestinal losses
  - Surgical bleeding
- Increased capillary permeability
  - Sepsis
  - Burns
  - Transfusion-related acute lung injury
- Decreased cardiac output
  - Myocardial ischemia or infarction
  - Cardiomyopathy
  - Valvular disease
  - Pericardial disease
  - Cardiac tamponade
  - Cardiac dysrhythmias
  - Pulmonary embolus
  - Tension pneumothorax
  - Drug induced (β-blockers, calcium channel blockers)
- Decreased vascular tone
  - Sepsis
  - Allergic reactions (anaphylactic, anaphylactoid)
  - Spinal shock (cord injury, iatrogenic high spinal)
  - Adrenal insufficiency

SYSTEMIC HYPOTENSION

Postoperative systemic hypotension may be characterized as (1) hypovolemic (decreased preload), (2) distributive (decreased afterload), (3) cardiogenic (intrinsic pump failure), and/or (4) extracardiac/obstructive. (Box 80.7).

Regardless of the type of shock the patient is in postoperatively, the underlying cause must be identified and treated. Fluids, blood products, and vasopressors can be used as needed to restore intravascular volume and support adequate perfusion while the patient is being assessed or undergoing a subsequent therapeutic procedure.

Hypovolemic (Decreased Preload)

Systemic hypotension in the PACU is often due to decreased intravascular fluid volume and preload, and, as such, it responds favorably to intravenous fluid administration. Common causes of decreased intravascular fluid volume in the immediate postoperative period include ongoing third-space translocation or loss of fluid, inadequate intraoperative fluid replacement (especially in patients who undergo major intraabdominal procedures or preoperative bowel preparation), and loss of sympathetic nervous system tone as a result of neuraxial (spinal or epidural) blockade.

Patients who are in hypovolemic shock often have typical associated clinical characteristics including tachycardia, tachypnea, hypotension, mottled skin (cool, clammy), venous collapse, decreased urine output, and altered mental status. The amount of volume loss tends to dictate clinical signs, as patients seem to be able to tolerate up to a 10% blood volume loss, with tachycardia being the only sign, whereas when patients lose around 40% of their total blood volume, clear signs of shock are evident (lactic acidosis, severe hypotension, reduced cardiac output).

Ongoing bleeding (hemorrhagic shock) should be ruled out in patients with hypotension who have undergone a surgical procedure in which significant blood loss was possible. Regardless of the estimated intraoperative blood loss, the measured blood loss may be inaccurate. If the patient is unstable, then hemoglobin can be measured at the bedside to eliminate laboratory turnover time. In addition, tachycardia may not be a reliable indicator of hypovolemia or anemia (or both) if the patient is taking β-blockers or calcium channel blockers. Non-hemorrhagic hypovolemia leading to hypotension can be a result of skin losses, especially in burn patients, and ascites, as in patients with liver failure or certain cancers (i.e., ovarian), GI fluid losses, secondary to vomiting and/or diarrhea and should be repleted with appropriate fluids as needed.

The potential for local anesthetic toxicity must be considered when assessing perioperative hypotension. Local anesthetics can become systemic secondary to accidental intravascular injection or following an overdose of injected medication +/− rapid absorption. Central nervous system signs, including tinnitus, confusion, altered mental status, and ultimately seizures may not always precede cardiovascular collapse. Once recognized, benzodiazepines should be given to abate seizures and supportive therapy should be instituted immediately to support cardiovascular function. Lipid emulsion therapy (20%) should be initiated, starting with a bolus of 1.5 mL/kg IV over 1 minute followed by a continuous rate of 0.25 mL/kg per minute for 30 minutes. Repeated boluses can be given every 5 minutes if cardiovascular collapse continues.

Distributive (Decreased Afterload)

Distributive shock in the PACU may be the result of a number of physiologic derangements, including iatrogenic sympathectomy, critical illness, allergic reactions, and sepsis. Iatrogenic sympathectomy, secondary to regional anesthetic techniques, is an important cause of hypotension in the perioperative period. A high sympathetic block (to T4) will decrease vascular tone and block the cardio-accelerator fibers. If not treated promptly, then the resulting bradycardia in the presence of severe hypotension can lead to cardiac arrest even in young healthy patients.[80] Vasopressors, including phenylephrine and ephedrine, are pharmacologic treatments of hypotension caused by residual sympathetic nervous system blockade.

Patients who are critically ill may rely on exaggerated sympathetic nervous system tone to maintain systemic blood pressure and heart rate. In these patients, even minimal doses of inhaled anesthetics, opioids, or sedative-hypnotics can decrease sympathetic nervous system tone and produce significant systemic hypotension.

Allergic (anaphylactic or anaphylactoid) reactions may be the cause of hypotension in the PACU. In addition to the sometimes-profound hypotension, patients experiencing an allergic reaction/anaphylaxis often present with an associated rash/hives, bronchospasm/wheezing, stridor, and facial edema. Patients should be treated immediately, with prompt removal of the offending agent if known and still present, steroids (hydrocortisone or methylprednisolone), H1 and H2 blockers, fluids, and vasopressors. Epinephrine is the drug of choice to treat hypotension secondary to an allergic reaction. Increased serum tryptase concentrations confirm the occurrence of an allergic reaction, but an elevated tryptase level does not differentiate anaphylactic from anaphylactoid reactions. The blood specimen for tryptase determination must be obtained within 30 to 120 minutes after the allergic reaction, but the results may not be available for several days. Neuromuscular blocking drugs are the most common cause of anaphylactic reactions in the surgical setting followed by latex, antibiotics, and other rare substances (Table 80.2).[81-83]

If sepsis is suspected as the cause of hypotension in the PACU, then blood should be obtained for culture, and empiric antibiotic therapy should be initiated as soon as possible. Urinary tract manipulation and biliary tract procedures are examples of interventions that can result in a sudden onset of severe systemic hypotension secondary to sepsis. Although fluid resuscitation is the most important immediate intervention, pressor support is often required—at least transiently. Norepinephrine is the pressor of choice in septic patients. Vasopressin deficiency has been shown to contribute to vasodilation in septic shock,[84] and low-dose vasopressin (0.01-0.05 unit/min) improves mean arterial pressure, decreases catecholamine vasopressor requirement, and may spare renal function in severe septic shock.[85]

TABLE 80.2 Drugs Involved in Perioperative Anaphylaxis

Substance	Incidence of Perioperative Anaphylaxis (%)	Most Commonly Associated With Perioperative Anaphylaxis
Muscle relaxants	69.2	Succinylcholine, rocuronium, atracurium
Natural rubber latex	12.1	Latex gloves, tourniquets, Foley catheters
Antibiotics	8	Penicillin and other β-lactams
Hypnotics	3.7	Propofol, thiopental
Colloids	2.7	Dextran, gelatin
Opioids	1.4	Morphine, meperidine
Other substances	2.9	Propacetamol, aprotinin, chymopapain, protamine, bupivacaine

From Hepner DL, Castells MC. Anaphylaxis during the perioperative period. *Anesth Analg*. 2003;97:1381–1395.

Cardiogenic (Intrinsic Pump Failure)

Significant cardiogenic causes of postoperative hypotension include myocardial ischemia and infarction, cardiomyopathy, cardiac tamponade, and cardiac arrhythmias. The differential diagnosis depends on the surgical procedure and the patient's preoperative cardiac risk and medical condition. To determine the cause of the hypotension, central venous pressure monitoring, echocardiography, and, rarely, pulmonary artery catheter monitoring may be required.

Patients can have a similar clinical appearance to those in hypovolemic shock; however one of the cardinal signs here is indication of relative fluid overload/congestive heart failure, such as distended central and peripheral veins, evidence of pulmonary edema, and a possible S3 heart sound on exam. These patients have elevated filling pressures in conjunction with reduced/impaired cardiac output. Cardiogenic shock can ensue when greater than 40% of the myocardium is damaged. Patients with underlying ischemic heart disease, especially if they are undergoing an emergent or high-risk procedure, are notably at increased risk of experiencing an adverse cardiac event. It should also be noted that the mortality rate for those in cardiogenic shock is remarkably high, reaching up to 70%. Patients may require immediate postoperative placement of an intra-aortic balloon pump (IABP), cardiac catheterization and stenting, echocardiography, or a surgical procedure for a mechanical/valvular abnormality.

Extracardiac/Obstructive Shock

Impairment in diastolic filling which ultimately results in decreased preload can lead to shock if not promptly recognized and treated. IVC compression (vena cava obstruction, intrathoracic tumors), tension pneumothorax, cardiac tamponade, constrictive pericarditis, and even PEEP/mechanical ventilation, can lead to diminished filling and compromise venous return. Intrathoracic tumors and tension pneumothoraces typically have similar clinical presentations to those in hypovolemic shock secondary to obstruction of the great veins, namely tachycardia and hypotension, possibly with associated distended neck veins. Patients in tamponade are also tachycardic and hypotensive; if they have indwelling invasive monitors, one typically can observe the "equalization of pressures" (increased and relatively equal LV and RV diastolic pressures, PAOP, CVP).

Acute pulmonary hypertension, pulmonary embolism, and aortic dissections result in impaired systolic contraction of the left and/or right ventricle secondary to increased afterload. These patients can present in either LV or RV failure, or even both.

Patients may need to undergo emergent needle thoracostomy and chest tube placement for a tension pneumothorax, a pericardiocentesis for tamponade, or thrombolysis/embolectomy for a pulmonary embolism.

Myocardial Ischemia: Evaluation and Treatment

Over 1 million people die every year after noncardiac surgery, with myocardial infarction being the most common cardiovascular complication.[86] The incidence of major adverse cardiac events depends on the number of inherent patient risk factors. According to the Revised Goldman Cardiac Risk Index, the risk of an adverse cardiac event can be as high as 5.4% after noncardiac surgery in patients who possess three or more risk factors.[87] Myocardial ischemia is rarely accompanied by chest pain in the recovery room secondary to the fact that patients are still emerging from anesthesia in the immediate postoperative period and are also still under the influence of residual medication effects, especially analgesics. In a study by Mangano et al., 94% of postoperative ischemic episodes were silent.[88]

EVALUATION

Patients who complain of chest pain in the recovery room should have a 12-lead ECG performed and a troponin level drawn. A physical exam and further workup, as indicated, should be done in order to rule out other causes for chest pain (e.g., pulmonary embolus, aortic dissection, tension pneumothorax, cardiac tamponade, esophageal rupture, etc.). ECG changes, such as ST-segment changes, may not necessarily represent myocardial ischemia (especially in younger patients with no known cardiac disease and no cardiac risk factors), however, should associated signs and symptoms point toward cardiac ischemia, further workup is certainly warranted.

Presently, myocardial ischemia after non-cardiac surgery (MINS) has been established as an entity in itself. MINS is defined as elevated postoperative troponin levels without any clinical symptoms or any changes in the ECG, provided there is no other nonischemic cause for the elevated troponin level (e.g., chronic troponin elevation, pulmonary embolism, sepsis, rapid atrial fibrillation). Elevated troponin levels are independently associated with poor outcomes.[89] An international prospective cohort study found that postoperative elevated troponin after noncardiac surgery was a strong independent predictor of 30-day mortality.[90]

The most recent guidelines established by the American Heart Association/American College of Cardiology (AHA/ACC) recommend obtaining a troponin level for all patients who present with ECG changes suggestive of ischemia or exhibit typical ischemic chest pain after surgery. Furthermore, they recommend drawing serial troponin levels for stable patients after vascular or intermediate risk surgery.[91] A recent multicenter study investigated the association between postoperative high-sensitivity troponin (hsTnT) levels with myocardial injury and 30-day mortality after noncardiac surgery.[92] The authors confirmed that postoperative myocardial injury is most commonly silent, as 93% of patients with MINS did not experience any symptoms. Furthermore, they found that elevated hsTnT levels without an ischemic feature in the first 3 days after noncardiac surgery were associated with a significantly increased 30-day mortality. These newer studies may even warrant a more liberal approach to drawing postoperative hsTnT levels in the PACU.

TREATMENT

Once the diagnosis of myocardial ischemia/injury has been made, the primary surgical team should immediately be notified and a cardiology consult should be obtained.

After ruling out other life-threatening causes, the patients should receive oxygen, and blood pressure and heart rate should be controlled. If there are no absolute contraindications to their administration, the patient should be given nitroglycerin, a β blocker, a statin, and aspirin. Pain and anxiety should be treated with an opioid and a benzodiazepine, and anemia should be corrected, if present. One should be prepared for further decompensation of the patient and have a code cart readily available. Should the patient become hemodynamically unstable, echocardiography may help in guiding next steps (e.g., placing an IABP, emergent interventions).

Depending on the acuity of the situation, further interventions like fibrinolysis, percutaneous coronary intervention (PCI), or revascularization should be considered and discussed. However, since these patients just had surgery, there are conflicting goals in terms of postoperative bleeding versus coronary blood flow. A mutual approach between surgeon, cardiologist, anesthesiologist, and patient should be chosen to determine the best course of action.

Cardiac Arrhythmias

Postoperative cardiac arrhythmias are frequently transient and multifactorial. Reversible causes of cardiac arrhythmias in the perioperative period include hypoxemia, hypoventilation and associated hypercapnia, endogenous or exogenous catecholamines, electrolyte abnormalities, acidemia, fluid overload, anemia, and substance withdrawal.[93]

TACHYCARDIA

Common causes of tachycardia in the PACU include pain, agitation, hypoventilation with associated hypoxia and hypercapnia, hypovolemia, PONV, and shivering. Less common but serious causes include hemorrhage; cardiogenic, septic, or anaphylactic shock; pulmonary embolism; pneumothorax; thyroid storm; and malignant hyperthermia.

When evaluating postoperative tachycardia, the most important question is whether or not the patient is hemodynamically stable. If the patient is stable, oxygen should be administered, a 12-lead ECG obtained, and the underlying rhythm determined. Unstable patients typically present with a heart rate greater than 150 bpm, are hypotensive, and may exhibit other signs of decreased perfusion, for example, altered mental status, chest pain, or shock. These patients should undergo immediate synchronized cardioversion. There are various different causes of tachyarrhythmia in the PACU which warrant individualized approaches regarding the medications to administer and the energy doses to use for cardioversion. A comprehensive overview can be found in the American Heart Association Guidelines Update for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care 2015.[94]

BRADYCARDIA

Bradycardia in the PACU is often iatrogenic. Drug-related causes include β-blocker therapy, anticholinesterase reversal of neuromuscular blockade, opioid administration, and treatment with clonidine or dexmedetomidine. Procedure- and patient-related causes include bowel distention, increased intracranial or intraocular pressure, hypoxia, hypothermia, hypothyroidism, and spinal anesthesia. A high spinal block can impede the cardioaccelerator fibers originating from T1 through T4, resulting in severe bradycardia. The ensuing sympathectomy and possible intravascular fluid volume depletion along with decreased venous return can produce sudden bradycardia and cardiac arrest, even in young healthy patients.

When evaluating postoperative bradycardia, vital signs and hemodynamic stability should be immediately assessed. Underlying causes should be corrected, if possible. Asymptomatic bradycardia may not need to be treated at all, however, if the patient is unstable and hypotensive, or shows signs of shock, altered mental status, ischemic chest discomfort, or acute heart failure, urgent intervention is indicated. According to the ACLS guidelines, first-line treatment is atropine IV. If this is ineffective, transcutaneous pacing or initiation of a vasopressor (dopamine, epinephrine infusion) is indicated. Eventually, expert consultation and transvenous pacing should be considered.[94]

ATRIAL ARRHYTHMIAS

The most common atrial arrhythmia is atrial fibrillation, which affects approximately 4% of patients following major noncardiac surgery.[95] The overall incidence of new postoperative atrial arrhythmias may be as high as 10% in this patient population. The incidence is even higher after cardiac and thoracic procedures when the cardiac arrhythmia is often attributed to atrial irritation.[96] The risk of postoperative atrial fibrillation is increased by preexisting cardiac risk factors, positive fluid balance, electrolyte abnormalities, and oxygen desaturation.[97] These new-onset atrial arrhythmias are not benign as they are associated with a longer hospital stay and increased mortality.[98,99]

Control of the ventricular response rate is the immediate goal in the treatment of new-onset atrial fibrillation. Hemodynamically unstable patients may require prompt electrical cardioversion, but most patients can be treated pharmacologically with an intravenous β-adrenergic blocker or calcium channel blocker.[100] If hemodynamic instability is a concern, the short-acting β-blocker esmolol can be considered. Rate control with these agents is often enough to chemically cardiovert the postoperative patient whose arrhythmia may be catecholamine driven. If the goal of therapy is chemical cardioversion, an amiodarone load can be initiated in the PACU with the knowledge that QT prolongation, bradycardia, and hypotension may accompany the intravenous infusion of this drug.

VENTRICULAR ARRHYTHMIAS

Premature ventricular contractions (PVCs) and ventricular bigeminy commonly occur in the PACU. PVCs most often reflect increased sympathetic nervous system stimulation that may accompany tracheal intubation, pain, and transient hypercapnia. They commonly resolve on their own, but this can be facilitated by administering analgesics and ensuring proper ventilation. True ventricular tachycardia is rare and is indicative of underlying cardiac pathology. In the case of torsades de pointes (polymorphic ventricular tachycardia), underlying QT prolongation on the ECG may be intrinsic or drug related. The most commonly administered QT prolonging drugs in PACU are 5-HT3 receptor antagonists (e.g., ondansetron, dolasetron), haloperidol, droperidol, albuterol, methadone, and amiodarone. Treatment with 1 to 2 g of magnesium IV over 5 minutes should be initiated and potentially repeated, if necessary.

TREATMENT

Early postoperative arrhythmias often require immediate electrolyte correction as well as pharmacologic and nonpharmacologic interventions.[101] In general, the urgency of treatment of a cardiac arrhythmia depends on the physiologic consequences of the arrhythmia, basically hypotension, cardiac ischemia, or both. Tachyarrhythmias decrease coronary perfusion time and increase myocardial oxygen consumption. Their impact depends on the patient's underlying cardiac function, and they are most harmful in patients with coronary artery disease. Bradycardia has a more deleterious effect in patients with a fixed stroke volume, such as infants and patients with restrictive pericardial disease or cardiac tamponade. For the most part, treatment relies on identifying and correcting the underlying cause (i.e., hypoxemia or electrolyte abnormalities).[102] The possible role of myocardial ischemia or the occurrence of pulmonary embolism must be considered when contemplating treatment options.

Renal Dysfunction

The differential diagnosis of postoperative renal dysfunction includes prerenal, intrarenal, and postrenal etiologies (Box 80.8). Frequently, the cause of renal insufficiency in the postoperative period is multifactorial, with an intraoperative insult exacerbating a preexisting renal insufficiency.[103-106] In the PACU, diagnostic efforts should focus on the identification and treatment of the readily reversible causes of oliguria (i.e., urine output less than 0.5 mL/kg/h). For example, urinary catheter obstruction or dislodgment is easily remedied and often overlooked (see Box 80.8). When appropriate, one should confer with the surgical team regarding the details of the surgical procedure (urologic or gynecologic) to rule out anatomic obstruction or disruption of the ureters, bladder, or urethra.

Patient-related factors play a role in the development of acute kidney injury (AKI) in the postoperative period. Comorbidities, such as preexisting renal insufficiency (CKD), diabetes mellitus, hypertension, morbid obesity, history of steroid use, male sex, and old age, are a number of

BOX 80.8 **Postoperative Oliguria**

Prerenal

Hypovolemia (bleeding, sepsis, third-space fluid loss, inadequate volume resuscitation)
Hepatorenal syndrome
Low cardiac output
Renal vascular obstruction or disruption
Intraabdominal hypertension

Renal

Ischemia (acute tubular necrosis)
Radiographic contrast dyes
Rhabdomyolysis
Tumor lysis
Hemolysis

Postrenal

Surgical injury to the ureters
Obstruction of the ureters with clots or stones
Mechanical (urinary catheter obstruction or malposition)

issues that should be taken into account when determining whether a patient is at an increased risk of perioperative renal dysfunction. In addition to nonmodifiable patient risk factors, the surgical procedure itself also comprises an independent risk factor in the development of perioperative renal dysfunction, with cardiac surgery, emergency surgery, and "major" surgery (vascular, transplant, thoracic) all serving to increase the probability.

A number of perioperative events may alter renal perfusion. Preoperative or intraoperative angiography can result in ischemic injury, secondary to renal vasoconstriction and direct renal tubular injury. Perioperative volume depletion can exacerbate hepatorenal syndrome or acute tubular necrosis caused by sepsis. The surgical procedure itself can alter renal vascular patency, decreasing renal perfusion. Finally, increased intraabdominal pressure (IAP) can impair renal perfusion.

Judicious intraoperative fluid management is of utmost importance both during the surgical procedure and in the postoperative period. Hemodynamics must be monitored to ensure that relative intravascular volume is sufficient to allow for tissue perfusion and avoidance of organ hypoxia and dysfunction. Crystalloid solutions are ubiquitous in the operating room and PACU. Balanced solutions (lactated Ringers, Plasmalyte) may be superior to chloride-only containing solutions (NaCl), as hyperchloremia is associated with the development of AKI.[107] A study published in Critical Care in 2014 revealed that chloride-liberal fluid administration was a risk factor in the development of postoperative AKI in liver transplant patients.[108] In general, hydroxylethyl starch solutions should be avoided, as there lacks any clear benefit to their use.[109]

A recent study published in Anesthesiology demonstrated that the risk of developing postoperative AKI was increased when the MAP was less than 60 for greater than 20 minutes or less than 55 for greater than 10 minutes.[110] As stated above, given the changes in renal autoregulation that occur over time in patients with hypertension, MAP goals should be tailored to each patient. Vasopressors may be needed as an adjunct to fluid therapy in hypotensive patients. To date, there is no evidence that one vasopressor is superior to another. It should be noted that even though low-dose dopamine can increase urine output, it is no longer deemed to be renoprotective and is not endorsed as a treatment strategy in AKI. Furthermore, vasodilator therapy (fenoldopam, atrial natriuretic peptide) is also not recommended in AKI prevention or treatment.

OLIGURIA

Intravascular Volume Depletion

The most common cause of oliguria in the immediate postoperative period is intravascular volume depletion. If the patient also demonstrates signs of hypovolemia, such as tachycardia and hypotension, a fluid challenge (500-1000 mL of crystalloid) is usually effective in restoring urine output. A CBC should be drawn if ongoing surgical blood loss is suspected and repeated fluid boluses are required to maintain adequate urine output. Patients with a history of hypertension may require higher MAPs to produce adequate urine. Their kidneys may not be perfused adequately with the standard "MAP > 65." In this patient population, it is imperative to review their baseline blood pressures and target a MAP greater than 75 mm Hg to ensure renal perfusion. Volume resuscitation to maximize renal perfusion is particularly important to prevent ongoing ischemic injury and the development of acute tubular necrosis. However, urine output does not predict the likelihood of developing postoperative AKI.

If a fluid challenge is contraindicated or oliguria persists, then assessment of intravascular fluid volume status and cardiac function is indicated to differentiate hypovolemia from sepsis and low cardiac output states. Fractional excretion of sodium can be useful in determining the adequacy of renal perfusion, assuming that diuretics have not been given. However, the diagnosis of prerenal azotemia will not differentiate hypovolemia, congestive heart failure, or hepatorenal syndrome. Further evaluation with central venous monitoring or echocardiography, or both, may facilitate the differential diagnosis.

Postoperative Urinary Retention

Postoperative urinary retention can cause bladder overdistention and permanent detrusor damage. Ultrasonography can measure bladder volume and identify urinary retention in the PACU.[111] Using this technique, Keita and associates attempted to identify patients at high risk by measuring bladder volume in 313 adult inpatients on admission to and before discharge from the PACU. They collected data on age, sex, history of urinary retention, intraoperative administration of anticholinergic agents, amount of intraoperative fluid administration, and intravenous use of morphine. Urinary retention was defined as bladder volume greater than 600 mL in conjunction with an inability to void within 30 minutes. In this study, the incidence of postoperative urinary retention in the PACU was 16%. The most significant predictive factors were age older than 50 years, intraoperative fluid more than 750 mL, and bladder volume on entry to the PACU greater than 270 mL.[112] This study argues for the use of ultrasound to identify patients at high risk for possible urinary retention.

CONTRAST NEPHROPATHY

Patients who have undergone angiography +/− intravascular stent placement for carotid stenosis, thoracic and abdominal aortic aneurysms, peripheral vascular disease, and cerebral aneurysms are increasing in numbers in our PACUs. As a result, contrast nephropathy should always be considered in the differential diagnosis of postoperative renal dysfunction and prompt diagnosis is crucial, as contrast nephropathy, in general, is one of the reversible causes of postoperative AKI. The creatinine tends to increase within 24 to 48 hours following the administration of contrast media, however return to the patient's baseline typically occurs within one week. Perioperative attention to adequate hydration is indicated in any patient who has received an intravenous contrast agent. Aggressive hydration with a balanced crystalloid solution is the single most effective means of protection against contrast nephropathy. Alkalinization of the urine with a sodium bicarbonate infusion and Mucomyst are sometimes used as well; however, beneficial evidence of these therapies is lacking and not well established.[113]

INTRAABDOMINAL HYPERTENSION

Intraabdominal hypertension (IAH) should be considered in any patient with oliguria and a tense abdomen on examination after abdominal surgery.[114,115] Elevated IAP can impede renal perfusion and lead to renal ischemia and postoperative renal dysfunction. Normal IAP in a patient who is not obese is approximately 5 mm Hg. Intraabdominal hypertension is graded into four categories: I: 12 to 15 mm Hg; II: 16 to 20 mm Hg; III: 21 to 25 mm Hg; and IV: greater than 25 mm Hg. Abdominal compartment syndrome is defined as an IAP greater than 20 mm Hg with or without an abdominal perfusion pressure less than 50 mm Hg.[116] Abdominal compartment syndrome (IAP usually >25 mm Hg) should be considered in patients with IAH that are exhibiting signs of new end organ dysfunction. In a prospective study of patients undergoing major abdominal surgery, intraabdominal hypertension accounted for 40% of new-onset renal insufficiency. In this study, postoperative renal impairment was independently associated with four factors: hypotension, sepsis, older age, and increased abdominal pressure.[117]

Elevation of IAP impairs venous drainage from the kidney, secondary to the increased vascular resistance that ensues when the renal vein is compressed. This cascade of events is responsible for the renal dysfunction that ultimately arises. When IAP reaches 15 mm Hg, oliguria tends to develop, whereas anuria is not common until pressures reach approximately 30 mm Hg. Management and treatment are mainly supportive (limiting extraneous fluids); however in severe cases, surgical decompression of the abdomen may be required.

Bladder pressure, an indirect assessment of IAP, should be measured in patients in whom intraabdominal hypertension is suspected to ensure the initiation of prompt intervention to relieve the pressure and therefore restore renal perfusion. Bladder pressure is measured at end expiration with the patient in the supine position and in the absence of abdominal muscle contractions. As with arterial pressure measurements, the transducer is placed in the midaxillary line.[117]

RHABDOMYOLYSIS

Rhabdomyolysis may complicate the postoperative course of patients who have suffered major crush or thermal injury. Patients may complain of myalgias, abdominal pain, nausea, and weakness. Myoglobinuria may be present and creatine kinase (CK) levels are elevated. The incidence is also significantly increased in morbidly obese patients undergoing bariatric surgery. Rhabdomyolysis has been reported to occur in 22.7% of 66 consecutive patients undergoing laparoscopic bariatric surgery.[118-121] Risk factors include increased BMI and the length of the surgery. Patient history and the operative course should guide the decision to measure creatine phosphokinase in the PACU.[119] Early, aggressive hydration to maintain urine output is the mainstay of treatment, as hypovolemia only serves to further intensify the impending renal failure secondary to renal ischemia and tubular obstruction from the heme casts. Electrolyte abnormalities, including hyperkalemia, hyperphosphatemia, and hypocalcemia must be detected and corrected immediately. Loop diuretics can be used to flush the renal tubules and to avoid fluid overload. The infusion of mannitol to enhance the elimination of myoglobin casts from the renal tubules and bicarbonate to protect against myoglobin toxicity is commonly practiced but may not provide further benefit. In a study of more than 2000 trauma patients with rhabdomyolysis, the infusion of bicarbonate and mannitol did not further decrease the incidence of acute renal failure.[121] In severe cases, an attempt can be made to remove myoglobin by continuous renal replacement therapy. Unlike conventional hemodialysis filters that do not remove circulating myoglobin, high-flux membranes can be effective. Continuous renal replacement modes typically use high-flux membranes. Additionally, convection (i.e., the mechanism of solute removal in continuous hemofiltration) removes larger molecular weight solutes than diffusion (i.e., the mechanism of solute removal in conventional hemodialysis).[122]

Postoperative Hypothermia and Shivering

Postoperative hypothermia, defined as a core temperature less than 36°C, is a detrimental and unpleasant condition that can occur after general and neuraxial anesthesia. According to the American Society of Anesthesiologists, the patient's temperature should be measured within 15 minutes after anesthesia end time and ideally be at least 36°C.[123] Postoperative shivering also often occurs after general and neuraxial anesthesia. The incidence of postoperative shivering may be as high as 66% after general anesthesia.[124] Identified risk factors include young age, endoprosthetic surgery, and core hypothermia.[125]

MECHANISM

Postoperative hypothermia occurs secondary to heat loss during surgery. Underlying mechanisms are radiation, convection, evaporation, and conduction.[126] Postoperative shivering is usually, but not always, associated with hypothermia. Although thermoregulatory mechanisms can explain shivering in the hypothermic patient, a number of different mechanisms have been proposed to explain shivering in normothermic patients. One proposed mechanism is based on the observation that the brain and spinal cord do not recover simultaneously from general anesthesia. The more rapid recovery of spinal cord function is thought to result in uninhibited spinal reflexes manifested as clonic activity. This theory is supported by the fact that doxapram, a central nervous system stimulant, is somewhat effective in abolishing postoperative shivering. Other proposed mechanisms include the action of kappa opioid, N-methyl-D-aspartate (NMDA), and 5-hydroxytryptamine receptors. The higher incidence of postanesthetic shivering in patients who receive high-dose remifentanil is thought to be by the same mechanism that causes hyperalgesia in these patients—sudden opioid withdrawal resulting in the stimulation of NMDA receptors.[127] Additional support for this theory comes from the same authors who found that a small dose of intraoperative ketamine reduced the incidence of remifentanil-induced postanesthetic shivering.[128] Tramadol, a weak μ-opioid receptor agonist, and norepinephrine and serotonin reuptake inhibitor, has been shown to be effective in preventing postoperative shivering while also contributing to analgesia.[129]

TREATMENT

Intervention includes the identification and treatment of hypothermia if present. Accurate core body temperatures can be most easily obtained at the tympanic membrane. Axillary, rectal, and nasopharyngeal temperature measurements are less accurate and may underestimate core temperature. Forced air warmers are used to actively warm the hypothermic patient. A number of opioids, ondansetron,[130] clonidine,[131] and ketamine[132] have been shown to be effective in abolishing shivering once it starts. Of those, meperidine, 12.5-25 mg IV, is most commonly used in adults. The intraoperative infusion of dexmedetomidine has been shown to be an effective prophylactic measure.[133]

CLINICAL EFFECTS

In addition to significant patient discomfort, so-called thermal discomfort, postoperative shivering increases oxygen consumption, CO_2 production, and sympathetic tone. It is associated with increased cardiac output, heart rate, systemic blood pressure, and intraocular pressure. Patients who are hypothermic on arrival in the PACU should be actively warmed to avoid these immediate complications as well as delayed consequences of hypothermia. Mild to moderate hypothermia (33°C-35°C) inhibits platelet function, coagulation factor activity, and drug metabolism. It exacerbates postoperative bleeding, prolongs neuromuscular blockade, and may delay awakening. Whereas these immediate consequences are associated with a prolonged PACU stay,[134] long-term deleterious effects include an increased incidence of myocardial ischemia and myocardial infarction, delayed wound healing, and increased perioperative mortality.

Postoperative Nausea and Vomiting

Without prophylactic intervention, roughly one third of patients who undergo inhalational anesthesia will develop PONV (range, 10%-80%).[135,136] The consequences of PONV include delayed discharge from the PACU, unanticipated hospital admission, increased incidence of pulmonary aspiration, and significant postoperative discomfort. The ability to identify high-risk patients for prophylactic intervention can significantly improve the quality of patient care and satisfaction in the PACU. From a patient's perspective, PONV may be more uncomfortable than postoperative pain.

PREVENTION AND TREATMENT

Prophylactic measures to prevent PONV include modification of anesthetic technique and pharmacologic intervention. In a randomized controlled multicenter multifactorial trial, Apfel and associates studied the efficacy of six prophylactic interventions in high-risk patients (PONV risk > 40%).[135] Interventions were both pharmacologic and technique related. Pharmacologic intervention included droperidol, 1.25 mg; dexamethasone, 4 mg; or ondansetron, 4 mg. Anesthetic intervention included propofol in lieu of volatile anesthetic, nitrogen in lieu of nitrous oxide, or remifentanil in lieu of fentanyl. More than 4000 patients were assigned to 1 of 64 possible combinations. The study found that each of the three antiemetics reduced the relative risk of PONV to the same degree (26%). Together, propofol (19% decrease) and nitrogen (12% decrease) reduced the relative risk of PONV to a similar degree.

Although prophylactic measures to prevent PONV are more effective than rescue measures, a subset of patients will require treatment in the PACU even after appropriate prophylactic treatment. There is no convincing evidence that any of the serotonin receptor antagonists commonly prescribed at this time are more effective than any others. Box 80.9 lists the different classes of antiemetic medications commonly prescribed for prophylaxis as well as treatment of PONV in the PACU. If an adequate dose of antiemetic given at the appropriate time is ineffective, simply giving more of the same class of drug in the PACU is unlikely to produce any significant benefit. Therefore, it is not recommended to redose any medication of the same class within 6 hours after the initial dose. Specific antiemetic medications such as scopolamine, dexamethasone, and aprepitant should not be redosed at all.[136]

The likelihood of a patient experiencing PONV depends on several risk factors and increases with the number of those factors that the patient possesses. Apfel et al. identified female gender, non-smoker, history of PONV/motion

BOX 80.9 Commonly Used Antiemetics (Adult Doses)

Anticholinergics

Scopolamine (1.5 mg) transdermal patch to a hairless area behind the ear before surgery (remove 24 h postoperatively)

NK-1 receptor antagonist

Aprepitant (40 mg per os within 3 h prior to anesthesia)

Corticosteroids

Dexamethasone (4 mg IV after induction of anesthesia)

Antihistamines

Hydroxyzine (12.5-25 mg IM)
Diphenhydramine (25-50 mg IV)

Phenothiazines

Promethazine (12.5-25 mg IM)
Prochlorperazine (5-10 mg IV)

Butyrophenones

Droperidol (0.625-1.25 mg IV); monitor the ECG for prolongation of the QT interval for 2-3 h after administration; preoperative 12-lead ECG recommended
Haloperidol (0.5-<2 mg IM/IV)

Prokinetic

Metoclopramide (10-20 mg IV; avoid if any possibility of gastrointestinal obstruction)

Serotonin Receptor Antagonists

Ondansetron (4 mg IV 30 min before the conclusion of surgery)

Vasopressors

Ephedrine (25 mg IM, combined with hydroxyzine, 25 mg)

sickness, and the need for postoperative opioids as independent risk factors. Their group has created a simplified risk score which predicts a likelihood to develop PONV of 10% for patients with no risk factor, 20% with 1 risk factor, 40% with 2 risk factors, 60% with 3 risk factors, and 80% with all four risk factors. More recently, the same author identified young age, defined as age below 50 years, as another independent risk factor for postdischarge nausea and vomiting.[137] The Society of Ambulatory Anesthesia published "Consensus Guidelines for the Management of Postoperative Nausea and Vomiting,"[136] which provides a great overview of the topic. The Prevention of PONV was added to the Physician Quality Reporting System of the Centers for Medicare and Medicaid Services. The goal is to give at least two different antiemetics to every patient older than 18 years undergoing any procedure under inhalational general anesthesia, if they have at least three risk factors for PONV.[138]

Emend (aprepitant), a substance P/neurokinin 1 receptor antagonist, may be effective in very high-risk patients and refractory cases. The recommended dose is 40 mg by mouth within 3 hours prior to anesthesia. Initial clinical trials have shown the drug to be effective for up to 48 hours after surgery.[139]

Delirium

Postoperative delirium (POD) is defined as an acute and fluctuating alteration of mental state of reduced awareness and disturbance of attention. POD often starts in the recovery room and can occur up to 5 days after surgery. One study found that many patients who were diagnosed with POD on the floor already had POD in the recovery room. The incidence of POD depends on peri- and intraoperative risk factors and is highly variable, for example, a meta-analysis of 26 studies of POD found an incidence ranging from 4.0% to 53.3% in hip fracture patients.[140] Multiple studies across different surgical specialties in elective and emergency cases have shown that POD is associated with worse surgical outcomes, increased hospital length of stay, functional decline, higher rates of institutionalization, higher mortality, and higher cost and resource utilization.[141] It is important to distinguish between the hyperactive and the hypoactive subtype of delirium, since the latter may easily go unnoticed, be therefore untreated, and potentially linked to a worse outcome.[142]

RISK FACTORS

POD has been linked to multiple risk factors. These are commonly distinguished between predisposing factors (inherent to the patient) and precipitating factors (triggering the onset of delirium). Major predisposing patient risk factors include (1) age greater than 65 years, (2) cognitive impairment, (3) severe illness or comorbidity burden, (4) hearing or vision impairment, and (5) presence of infection.[143] In the perioperative context, the performed surgical procedure acts as a physiologic stressor with the extent of surgery having a major impact on the likelihood of developing delirium. Risk assessment is a shared clinical responsibility and should ideally be implemented in a perioperative clinical pathway.

PROPHYLAXIS AND MANAGEMENT

Patients at high risk of POD should ideally be identified prior to entering the operating room by using a delirium risk screening tool. Patients who screen positive should potentially go on a delirium reduction pathway to decrease their likelihood of developing delirium in the postoperative phase. Once in the recovery room, any deliriogenic medications should be avoided (e.g., anticholinergics, sedative-hypnotics, meperidine), unless the specific needs for any of these medications outweigh their potential risks (e.g., benzodiazepines for benzodiazepine or alcohol withdrawal).[144] Simple measures, such as frequent reorientation, sensory enhancement (ensuring glasses, hearing aids, or listening amplifiers are available upon arrival in the PACU), pain control, cognitive stimulation, simple communication standards and approaches to prevent the escalation of behaviors, and keeping the patients in their circadian rhythm can decrease the incidence of developing POD by 30% to 40%.[144] Screening for delirium in the PACU should be performed before the patient leaves the unit (e.g., with the Nursing Delirium Screening Scale or Confusion Assessment Method score).

If prevention has failed and the patient screens positive, prompt evaluation of possible precipitating factors should occur. These include uncontrolled pain, hypoxia, pneumonia, infection (wound, indwelling catheter and blood stream, urinary tract, sepsis), electrolyte abnormalities, urinary retention, fecal impaction, medications, and hypoglycemia.[141] Treatment of causative factors and symptoms has a major impact on reducing the duration of delirium and should therefore be initiated immediately. Generally, multicomponent nonpharmacologic interventions should be used for all delirious patients (e.g., frequent reorientation, calm environment, eliminating restraint use, familiar objects in the room, bringing glasses and hearing aids to the patient). Pharmacologic interventions should be reserved and only used in the lowest effective dose for agitated delirious patients when other interventions have failed and the patients pose a substantial harm to themselves or others. The medication of choice in this case is haloperidol starting at 0.5 to 1 mg IM/IV. Alternatively, atypical antipsychotics like risperidone, olanzapine, quetiapine, or ziprasidone can also be considered.[141]

Emergence Excitement

Persistent POD should not be confused with emergence “excitement,” a transient confusional state that is associated with emergence from general anesthesia. Emergence excitement is common in children, with more than 30% experiencing agitation or delirium at some period during their PACU stay. It usually occurs within the first 10 minutes of recovery but can have onset later in children who are brought to the recovery room asleep. The peak age of emergence excitement in[145] children is between 2 and 4 years. Unlike delirium, emergence excitement typically resolves quickly and is followed by uneventful recovery.[146]

In children, emergence excitement is most frequently associated with rapid “wake up” from inhalational anesthesia. Although it has also been reported after isoflurane[147] and, to a lesser extent, halothane[148] anesthesia, it is most often associated with the less-soluble vapors sevoflurane[149] and desflurane. Several studies suggest that the incidence of emergence excitement is more a reflection of the anesthetic agent used rather than the rapidity of emergence.[150] In studies comparing sevoflurane and propofol, propofol resulted in a much smoother awakening than sevoflurane despite rapid emergence. Furthermore, delaying emergence by a slow reduction in the inhaled concentration of sevoflurane did not reduce the incidence of emergence excitement.[151]

In addition to rapid emergence, the literature supports a number of possible etiologic factors, including intrinsic characteristics of the anesthetic, postoperative pain, type of surgery, age, preoperative anxiety, underlying temperament, and adjunct medications. Awareness of these contributors allows one to identify and treat children who are at increased risk.[146]

Simple preventative measures should be taken to treat children at risk. These include reducing preoperative anxiety, treating postoperative pain, and providing a stress-free environment for recovery. Medications that have been used to prevent and treat emergence agitation/delirium in children include midazolam,[152] clonidine,[153-155] dexmedetomidine,[156,157] fentanyl,[158,159] ketorolac,[160] and physostigmine.[161] In children, the most common preoperative anxiolytic, midazolam, has produced conflicting data. Although midazolam is generally associated with a decrease in the incidence and duration of POD, not all studies are in agreement. In studies in which it has not been shown to be beneficial, it is unclear whether midazolam is an independent factor or merely a reflection of other preoperative variables.[162]

The incidence of emergence excitement in adults is significantly less than in children. It is estimated to be between 3% and 4.7%.[163] One study found that significant surgical- and anesthesia-related risk factors included preoperative medication with midazolam (OR 1.9), breast surgery (OR 5.2), abdominal surgery (OR 3.2), and, to a much lesser extent, length of surgery.[163]

Delayed Awakening

Even after prolonged surgery and anesthesia, a response to stimulation in 60 to 90 minutes should occur.[164] If emergence has not taken place at that point, it is important to consider multiple different reasons as the possible underlying cause. Residual drug effects are the most frequent cause of delayed emergence and may occur after too much anesthetic has been given or in a patient who is susceptible to the side effects of certain medications due to age, underlying disease, or metabolic derangements. The most common drugs to consider are benzodiazepines, opioids, and neuromuscular blocking drugs, however, after a very long anesthetic, propofol and volatile anesthetics can also cause a delay in emergence. Furthermore, acute alcohol or illicit drug intoxication can be other culprits. Another often overlooked drug effect is the central anticholinergic syndrome (CAS). Several drugs used during anesthesia can block the central cholinergic neurotransmission and therefore delay the wakeup.[165] Metabolic disturbances such as hypothermia (<33°C), electrolyte imbalances (e.g., hyponatremia, hypercalcemia, hypermagnesemia), hypo- or hyperglycemia, as well as underlying metabolic diseases (e.g., liver, kidney, or thyroid abnormalities) can delay emergence after anesthesia. Finally, neurologic complications such as cerebral hypoxia, seizures (with consecutive postictal state), elevated ICP, as well as any intracerebral event (hemorrhage, thrombosis, embolus) should be considered.[166,167]

In any patient who presents with a delayed emergence, airway, breathing, and circulation should be assessed. It is important to confirm that all anesthetic agents are discontinued (including residual agents left in the IV tubing). The patient’s body temperature should be checked upon arrival in the PACU and if hypothermia is present, the patient should be actively rewarmed. A cardiopulmonary as well as a neurologic exam (including pupils, cough and gag reflex, motor/strength) should be performed. The use of a neuromuscular transmission monitor (TOF, ideally TOF-R) is instrumental in detecting residual neuromuscular blockade, which should be reversed (with either neostigmine/glycopyrrolate or sugammadex). If a residual opioid effect is suspected, naloxone in small increments (40 µg every 2 minutes up to 200 µg) can be titrated to effect. Equally, if a residual benzodiazepine effect is suspected, flumazenil in 0.1 to 0.2 mg increments every 1 minute up to 1 mg can be titrated to effect. A blood glucose level should be checked and hypoglycemia should be treated with dextrose, whereas hyperglycemia can be treated with insulin as needed. An ABG and electrolyte panel should be obtained. CO_2 narcosis can be treated with hyperventilation (and potentially intubation), and electrolyte disturbances should be corrected. If none of the above interventions yields any suspicious results, CAS should be considered and physostigmine 1 to 2 mg IV could be administered. At the same time, it is important to rule out any cerebrovascular accident by consulting neurology and obtaining a stat head CT. If the patient still does not emerge, admission to the ICU for further monitoring and serial exams should be initiated.

Discharge Criteria

Although specific PACU discharge criteria may vary, certain general principles are universally applicable (Box 80.10).[2] To summarize, a mandatory minimum stay in the PACU is not required. Patients must be observed until they are no longer at risk for ventilatory depression and their mental status is clear or has returned to baseline. Hemodynamic criteria are based on the patient's baseline hemodynamics without specific systemic blood pressure and heart rate requirements. An assessment and written documentation of the patient's peripheral nerve function on discharge from the PACU may become useful information should a new peripheral neuropathy develop in the later postoperative period.

POSTANESTHESIA SCORING SYSTEMS

In 1970, Aldrete and Kroulik developed a postanesthesia scoring system to monitor recovery from anesthesia. The original Aldrete score assigned a number of 0, 1, or 2 to 5 variables: activity, respiration, circulation, consciousness, and color. A score of 9 out of 10 was considered adequate for discharge from the PACU.[168] Over the years, this system has been modified to keep up with advances in technology and anesthesia practice, including the expansion of ambulatory surgery. In 1995, pulse oximetry replaced visual assessment of oxygenation and additional assessments were added to accommodate patients undergoing ambulatory surgery (Tables 80.3 and 80.4).[169]

With the increase in number and complexity of outpatient surgeries, discharge criteria have been amended by various authors to include assessment of home readiness. The resulting PADSS, or postanesthesia discharge scoring system, continues to evolve. It was initially based on five criteria: vital signs, ambulation and mental status, pain and nausea/vomiting, surgical bleeding, and fluid intake/output. The current version has been modified to separate pain and nausea/vomiting and to eliminate the need to urinate before discharge.[170-174] In the ambulatory

BOX 80.10 Summary of Recommendations for Discharge

1. Patients should be alert and oriented or mental status returned to baseline.
2. A minimum mandatory stay is not required.
3. Vital signs should be stable and within acceptable limits.
4. Discharge should occur after patients have met specified criteria.
5. Use of scoring systems may assist in documenting fitness for discharge.
6. The requirement to urinate before discharge and drink and retain clear liquids should *not* be part of a routine discharge protocol, although these requirements may be appropriate for selected patients.
7. Outpatients should be discharged to a responsible adult who will accompany them home.
8. Outpatients should be provided with written instructions regarding postprocedure diet, medications, activities, and a telephone number to call in case of emergency.

Modified from American Society of Anesthesiologists Task Force on Postanesthetic Care. Practice Guidelines for Postanesthetic Care: a report by the American Society of Anesthesiologists Task Force on Postanesthetic Care. *Anesthesiology*. 2002;96:742–752.

TABLE 80.3 Criteria for the Determination of Discharge Score for Release from the Postanesthesia Care Unit

Variable Evaluated	Score
ACTIVITY	
Able to move four extremities on command	2
Able to move two extremities on command	1
Able to move no extremities on command	0
BREATHING	
Able to breathe deeply and cough freely	2
Dyspnea	1
Apnea	0
CIRCULATION	
Systemic blood pressure ≤20% of the preanesthetic level	2
Systemic blood pressure is 20% to 50% of the preanesthetic level	1
Systemic blood pressure ≥50% of the preanesthetic level	0
CONSCIOUSNESS	
Fully awake	2
Arousable	1
Not responding	0
OXYGEN SATURATION (PULSE OXIMETRY)	
Greater than 92% while breathing room air	2
Needs supplemental oxygen to maintain saturation >90%	1
Less than 90% with supplemental oxygen	0

Modified from Aldrete JA. The postanaesthesia recovery score revisited. *J Clin Anesth*. 1995;7:89–91.

TABLE 80.4 Criteria for Determination of Discharge Score for Release Home to a Responsible Adult

Variable Evaluated	Score*
VITAL SIGNS (STABLE AND CONSISTENT WITH AGE AND PREANESTHETIC BASELINE)	
Systemic blood pressure and heart rate within 20% of the preanesthetic level	2
Systemic blood pressure and heart rate 20% to 40% of the preanesthetic level	1
Systemic blood pressure and heart rate >40% of the preanesthetic level	0
ACTIVITY LEVEL (ABLE TO AMBULATE AT PREOPERATIVE LEVEL)	
Steady gait without dizziness or meets the preanesthetic level	2
Requires assistance	1
Unable to ambulate	0
NAUSEA AND VOMITING	
None to minimal	2
Moderate	1
Severe (continues after repeated treatment)	0
PAIN (MINIMAL TO NO PAIN, CONTROLLABLE WITH ORAL ANALGESICS; LOCATION, TYPE, AND INTENSITY CONSISTENT WITH ANTICIPATED POSTOPERATIVE DISCOMFORT)	
Acceptability:	
Yes	2
No	1
SURGICAL BLEEDING (CONSISTENT WITH THAT EXPECTED FOR THE SURGICAL PROCEDURE)	
Minimal (does not require dressing change)	2
Moderate (up to two dressing changes required)	1
Severe (more than three dressing changes required)	0

*Patients achieving a score of at least 9 are acceptable for discharge.
Modified from Marshall SI, Chang F. Discharge criteria and complications after ambulatory surgery. *Anesth Analg*. 1999;88:508–517.

surgery setting, postoperative pain is the most significant cause of delayed discharge and unplanned hospital admission. In an effort to improve patient satisfaction and timely discharge, Chung and associates identified a subset of high-risk patients who are likely to benefit from intense prophylactic analgesic therapy. This study of 10,008 consecutive ambulatory surgical patients found that the incidence and intensity of postoperative pain increased with increasing BMI and duration of anesthesia. Orthopedic and urologic procedures were the most significant surgical factors.[175]

PACU Standards of Care require that a physician accept responsibility for the discharge of patients from the unit (Standard V).[1] This is the case even when the decision to discharge the patient is made at the bedside by the PACU nurse in accordance with hospital-sanctioned discharge criteria or scoring systems. If discharge criteria are to be used, they must first be approved by the department of anesthesia and the hospital medical staff. A responsible physician's name must be noted on the record.

Infection Control

Limitations in space,[161] staffing,[176,177] and time contribute to the transmission of infectious organisms in the PACU. The PACU is typically an open unit without physical barriers between bed stations, however many units, such as those at Massachusetts General Hospital (MGH), have transitioned to individual rooms with doors. There are also a number of both positive and negative pressure specific rooms. Nurses and respiratory therapists simultaneously care for more than one patient, and admissions to the unit are transient with a length of stay measured in hours rather than days. Infection control monitoring can be difficult, as an infection that is transmitted as a result of a lapse in proper infection control in the PACU might not be identified by routine monitoring until days later on the inpatient unit.

Standard precautions, which are known as the absolute minimum method of infection control, should always be followed when encountering each patient.[178,179] Hand hygiene, which encompasses washing the hands with an antimicrobial soap or the use of alcohol-based hand rub (ABHR), is the single most important and effective component of preventing contamination between patients and should be employed both before and after patient contact.[180,181] Proper hand hygiene is required even if the caregiver is wearing gloves. The installation of bedside alcohol-based cleansers increases compliance of hand hygiene among heathcare workers in the ICU.[182-185] Although no equivalent study has been conducted in the PACU, the unit is similar to the ICU in workload and intensity of patient care. The Centers for Disease Control and Prevention's Guideline for Hand Hygiene in Health-Care Settings recommends that an "alcohol based hand rub [be made] available at the entrance to the patient's room or at the bedside, in other convenient locations, and in individual pocket-sized containers to be carried by [healthcare workers] HCWs."[186] Although the convenience of appropriately placed alcohol-based cleansers is expected to improve hand-cleansing compliance, no follow-up studies in the PACU have been published.

With these limitations in mind, it is not surprising that the PACU has been described as the "weakest link" in the chain of care that bridges the sterile technique practiced in the operating room with infection control protocols practiced on the surgical unit. Despite an awareness of the factors that increase the risk of infection in the PACU, no studies have addressed the problem until recently. A study of hand cleansing during postanesthesia care documents the poor compliance of PACU nurses with this standard infection control procedure.[182,187] In this observational study of 3143 patient care activities, the average compliance with hand cleansing was only 19.6% on patient admission to the unit and 12.5% in patients already admitted to the unit. In this study, the intensity of patient care activities was an independent predictor of noncompliance; that is, the greater the workload, the less likely the nursing staff would comply with infection control measures. Additional independent factors included patients of advanced age (65 years and older) and those recovering from clean surgery (i.e., surgical sites in which the respiratory, alimentary, and urinary tracts are not entered) and clean-contaminated surgery (i.e., surgical sites in which

TABLE 80.5 Infectious Agent Precautions

Droplet Precautions	Airborne Precautions
Neisseria meningitides (meningitis)	Tuberculosis (TB)
Group A Streptococcus	Varicella virus (chickenpox)
Rubella (German measles)	Variola virus (smallpox)
Mumps virus	Influenza A
Corynebacterium diphtheria (pharyngeal diphtheria)	Hemorrhagic Fever viruses (Ebola, Marburg, Lassa)
Bordetella pertussis (whooping cough)	Rubeola virus (measles)
Yersinia pestis (pneumonic plague)	SARS

respiratory, alimentary, genital, or urinary tracts are entered under controlled conditions without unusual contamination). As expected, compliance was best in patients with contaminated or known infected wounds.

There are three primary modes of transmission of infectious agents: contact (direct or indirect), droplet, and airborne. The most common way pathogens are transmitted is via contact. In direct contact, organisms are transmitted directly from one person to another usually via blood or bodily fluids. Contact Plus (IE: C difficile infections) requires the healthcare worker to both wash their hands and use ABHR. Droplet transmission occurs when the source coughs or sneezes and usually requires relatively close contact for the other person to become infected as droplets (large particle, >5 mm) do not remain suspended in the air for greater than three feet. Airborne transmission occurs when small particle droplets (<5 mm) are disseminated into the air, can remain there for longer periods of time, and have the ability to travel further as compared to large particles. Patients with known or suspected airborne infections should be placed in negative pressure rooms. Healthcare workers are required to wear N95 masks when they are caring for a patient with tuberculosis (Table 80.5).

Postoperative Management of Patients Undergoing Transcatheter Aortic Valve Replacement and Transcatheter Mitral Valve Repair

Transcatheter aortic valve implantation (TAVI) was first described in 2002 and was touted as a less invasive surgical option in those with severe aortic stenosis when compared to the classic approach of an aortic valve replacement. In brief, this procedure involves the deployment of a prosthetic valve within the native, stenotic aortic valve via a catheter that is inserted into the femoral, iliac, or subclavian artery. Classically, these patients have been admitted to an ICU postoperatively; however, as the volume of these patients increases and with continued advances in surgical technique, many patients are now extubated in the operating room and have ICU lengths of stay less than 24 hours (Table 80.6).[188] Given the ever-expanding need for ICU beds, some of these patients are now brought to the PACU to recover. We have recently developed a pathway at MGH designed for specific patients to recover in the PACU, instead of going to the cardiac surgical ICU (SICU). Currently, we are relatively selective with regard to the specific patients we recover in the PACU and those who will be admitted to the ICU postoperatively.

TABLE 80.6 Massachusetts General Hospital's Indications for Admission to the Intensive Care Unit After Transcatheter Aortic Valve Implantation

Preoperative	Intraoperative
Transapical approach	Expected postoperative intubation
Transaortic approach	Unexpected placement of a PA line
Need for preoperative hemodynamic support	Hemodynamic instability
Emergency case	Conditions requiring close monitoring (pericardial fluid, aortic injury)
Pulmonary artery catheter needed postoperative	Ischemia
Preoperative significant delirium	Significant arrhythmia
Significant pulmonary hypertension	Suspected complete heart block without adequate safe pacing
High-grade coronary artery disease	

PA, Pulmonary artery.

Patients who undergo TAVIs are typically older and have a significant number of comorbidities, including coronary artery, peripheral vascular, and/or cerebrovascular disease, as well as COPD and pulmonary hypertension.[189,190] For the purpose of this chapter, only the immediate postoperative issues that are most commonly encountered in the PACU will be described. For a comprehensive review of ICU care following TAVI, please see chapter 54.

As with any cardiac procedure, the postoperative period may be complicated by neurologic issues (pain, altered mental status, cerebrovascular accident), cardiac issues (hemodynamic instability, arrhythmias, ischemia), and vascular access issues (bleeding). The average age at MGH of patients who undergo TAVI is 82, and the average age was 83 in the PARTNER trial.[189] POD is a well-known complication in older individuals undergoing cardiac surgery[188] and POD is associated with increased ICU and hospital length of stay, as well as increased mortality. Preventative measures to help reduce delirium, such as frequent reorientation, natural light, minimizing lines and tubes, and promoting a normal sleep-wake cycle should be utilized as often as possible. ICU stay is an independent risk factor for delirium, and simply bypassing the ICU via recovering in the PACU and discharging the patient to the floor may help decrease the incidence of delirium in this patient population. If necessary, the use of antipsychotics may be used to treat delirium, however many are associated with QT prolongation which can predispose this already fragile patient population to arrhythmias. Dexmedetomidine may be used to prevent delirium, however its associated hypotension and bradycardia may require intervention with regard to vasopressor support. When managing postoperative pain, every attempt to minimize narcotics should be undertaken, as narcotics are associated with increased delirium in the elderly. At MGH with TAVIs via the femoral route, we have found that patients do not often complain of severe pain and are easily managed with acetaminophen and occasional low-dose fentanyl. These patients also require close monitoring —hence monitoring in the PACU for mental status changes with frequent performance of neurological exams, as the risk of stroke is the highest within the first 24 hours post-TAVI neurological event should be immediately evaluated.[191,192] These embolic events are most likely embolic secondary to the nature of the procedure and likelihood for embolization of calcium and microthrombi.

After undergoing a TAVI, the ejection fraction and cardiac output will increase. These changes are generally well tolerated. Pacing wires are used intraoperatively to allow for rapid ventricular pacing during valve deployment. These wires may be left in postoperatively in patients who either go into complete heart block and have not had a permanent pacemaker (PPM) placed intraoperatively. The PARTNER trial demonstrated that patients who undergo TAVI are more likely to require PPM placement than those who undergo surgical aortic valve replacement.[193,194] New-onset atrial fibrillation is also a common occurrence post-TAVI, however most patients are not anticoagulated given they will be started on dual antiplatelet therapy and the known association with increased risk of bleeding and even death.[195,196]

Vascular access site complications are a familiar occurrence following TAVI and can include retroperitoneal hemorrhage, arterial dissection, or pseudoaneurysm formation. Removal of arterial sheaths requires proper technique and includes the application of pressure at the insertion site for an appropriate amount of time.[188]

The first procedure involving transcatheter mitral valve repair (with the MitraClip) was performed in 2003. MitraClips are a minimally invasive alternative to open valvular surgery in those who suffer from mitral regurgitation. The number of these procedures performed at MGH is less than the patients who undergo TAVI, however, within the last year we have started to recover these patients in the PACU as well. Postoperative complications to be aware of are similar to TAVIs. Bleeding is one of the most common adverse events[197,198] and ample pressure must be applied when the femoral venous catheter is removed. These patients commonly have atrial fibrillation, necessitating anticoagulation therapy, which only serves to further amplify the risk of bleeding, and not only from the vascular access site (i.e., GI hemorrhage). Patients who are not on anticoagulation therapy will typically receive dual antiplatelet therapy for one month postprocedure.[199] Fortunately, pericardial tamponade remains a rare occurrence, as does the risk of clip migration and partial clip detachment.[197,198]

It appears as though patients who undergo both TAVI and MitraClip procedures can recover in the PACU. Caregivers must be aware of, and remain mindful of, potential procedural complications.

Immediate Postoperative Care of Craniotomies

In many institutions, it is the standard of care to admit patients to the neurosurgical intensive care unit (NICU) after any type of craniotomy. However, it has never been shown that this improves patients' outcomes and lately several authors have questioned this approach. The number of NICU beds is limited and certain patients may not require this elevated level of acuity, such as those who undergo minor craniotomies.[200] Instead, the patients are admitted to the PACU and after they meet discharge criteria, are transferred to a lower acuity ward (neurosurgical transitional care unit [NTCU]). This approach may decrease the average hospitalization length of these patients and also provide substantial cost savings.[201] The goal is to reduce the demand for NICU beds and allocate resources more effectively to those for whom they are appropriate.

This is an evolving issue and obviously local conditions and policies have to be taken into account. First and foremost, the neurosurgeons have to agree to have their patients on this pathway. Furthermore, clear criteria for patients to get on this pathway have to be developed. Currently, at University of California, San Francisco (UCSF), we use a "Safe Transition Pathway" where we apply several criteria to determine whether or not a patient can safely bypass the ICU. Besides taking type of surgery, patient's age, comorbidities (especially those that would warrant postoperative ICU level of care), the duration of the procedure, and the estimated blood loss (EBL) during surgery into account,[202] we also only consider tumors below a certain size eligible for our pathway at UCSF. Furthermore, in order to remain on this pathway, no adverse intraoperative events should occur and the patient should have had an uneventful routine intubation and extubation.[203] There should not be any concerns regarding bypassing the NICU from the surgical and anesthesia teams during the debriefing at the end of surgery.

Patients on this pathway need some closer attention in the PACU. During the sign-out, the baseline neurologic examination prior to surgery should be conveyed to the PACU team (e.g., motor function, any deficits, patient conversant), as well as anticipated or expected deficits given the location of the procedure. Explicit hemodynamic goals should be clarified, especially upper limit for SBP or MAP, since even minor bleeding can have devastating consequences. Drugs to treat postoperative hypertension are either labetalol or a nicardipine infusion, since these medications do not increase cerebral vasodilation. A pupillary exam should be performed upon arrival in PACU, with the goal to rule out significant anisocoria or a unilateral, fixed, dilated pupil. Bilateral miosis is not uncommon and may be attributed to intra- and postoperative opioid administration. During the PACU stay, the head of the bed is typically elevated to promote cerebral venous drainage. Significant neck manipulation should be limited, since this can impair venous drainage. Airway obstruction and apnea should be avoided, since an increase in $PaCO_2$ will cause cerebral vasodilation and increase the intracerebral pressure (ICP). For the same reason oxygenation should be maintained, since hypoxemia will also increase the ICP. Coughing and bucking is best avoided, too, since they can also cause acute elevation of the ICP.

Common issues that can arise in the PACU in this patient population include altered mental status, which warrants frequent reassessment and examination, especially for any motor deficits. Seizures can be observed even in previously healthy patients without a history of epilepsy, since the surgical manipulation of the brain and dura are highly irritating and do increase the risk of these occurring. The clinician's primary focus should be on terminating the seizures with IV benzodiazepines (lorazepam, midazolam) and maintaining a patent airway. Endotracheal intubation should be considered if protection of the airway in the postictal state is not possible in order to avoid hypercarbia and hypoxia. This would obviously require the patient to be transferred to the NICU. Nonsurgical causes for a seizure (e.g., hypoglycemia or electrolyte imbalance) should always be considered and ruled out. In terms of postoperative pain, headaches and neck pain are not uncommon after craniotomies, although the pain is usually not severe. Acetaminophen and low-dose opioids should be the first choice of analgesics. NSAIDs should be used either with caution or not at all in the acute postoperative setting, since they can cause intracerebral bleeding. The primary surgical team should always be consulted before the administration of any NSAIDs. Finally, PONV can occur in this patient population as well and should be treated aggressively since retching and vomiting can cause a transient increase of the ICP.

The patients will typically stay in the PACU until the routine criteria for transfer to the NTCU are met and they will continue to be monitored and examined very closely and should have telemetry and continuous pulse oximetry ordered.

Potentially Devastating Visual Complications

CORNEAL ABRASIONS

Corneal abrasions (CAs) are the most common ophthalmic injury in the postoperative period with an incidence ranging from 0.17% to 44%.[204] Many CAs are secondary to mechanical trauma and patients often complain of blurry vision, tearing, redness, photophobia, and foreign body sensation in the eye. Corneal epithelial cells are self-regenerating, and therefore CAs tend to resolve quickly with limited treatment and long-term complications are uncommon. However, the injury is unexpected, painful, and anxiety-inducing for the patient. Statistically significant risk factors include age, general anesthesia, greater average EBL, eyes taped during surgery, prone position, Trendelenburg position, and supplemental oxygen on the way to and in the PACU.[204] Minor CAs do not necessarily need to be evaluated by an ophthalmologist; several institutions have developed treatment protocols in conjunction with their ophthalmology department. According to these protocols, minor CAs can usually be treated by anesthesiologists, who can diagnose them and initiate a pre-established treatment regimen. However, should the patient have any vision loss, change in visual acuity, severe or uncontrolled pain, a history of refractive eye disease, a large or complicated abrasion or a foreign body, an ophthalmology consult should immediately be initiated. If the patients receive the pre-established treatment regimen, their symptoms should be resolved by the next morning, which can be confirmed with a follow-up phone call; otherwise they should be evaluated by an ophthalmologist.[204,205]

POSTOPERATIVE VISION LOSS

Postoperative vision loss (POVL) is a rare but devastating complication after anesthesia. The etiology is multifactorial (e.g., CA, ischemic optic neuropathy [ION], cerebral vision loss, central retinal artery occlusion, and several other less common causes) and POVL can occur after any surgical procedure. However, there seems to be an increased incidence after spinal fusions and cardiac surgeries. ION is the most common cause of permanent POVL and accounts for 89% of POVL following prone spine surgeries.[206] The incidence of ION has decreased by over 50% from 1.63/10,000 (1998–2000) to 0.6/10,000 (2010–2012).[207] Risk factors for ION have been identified and include: male gender, obesity, use of Wilson frame, long surgery/anesthesia (>6.5 hours), high EBL (>45% of estimated blood volume), and lower percent colloid administration.[208,209] If POVL is suspected, immediate ophthalmologic consultation should be sought. However, the long-term outcome of this complication is unfortunately usually poor.[210]

Future Considerations

INTENSIVE CARE

In recent years, the demand for ICU beds has increased significantly within the United States and Europe. Because the PACU possesses the equipment and expertise to monitor, ventilate, and resuscitate patients recovering from general anesthesia, it has become the logical choice to provide care for critically ill patients for whom ICU beds are not available.[211] Although it is now common to care for critically ill patients in the PACU, the maintenance of quality patient care continues to challenge hospital administrators and staff.[212]

One obstacle to efficient ICU care in the PACU is the diversity of physician coverage required. Whereas the proximity of the operating room and the patient population recovering from anesthesia dictate that an anesthesiologist be the responsible physician for the majority of patients in the unit, nonsurgical ICU patients often require physician coverage by specialists who are unfamiliar with the unit and whose practices are located in distant areas of the hospital. As a result, PACU nurses must identify and contact physicians with whom they rarely interact.

Physician coverage (who will be primarily responsible for patient care—internist, anesthesiologist, or surgeon), privacy for family visitation (lack of space in a traditionally open unit), infection control (the proximity of patient beds and rapid turnover of patients), and nursing competencies (ongoing ICU training of staff) are some of the challenges facing the PACU today.[213] In a study of 400 ICU overflow patients admitted to the PACU in the United Kingdom, Ziser and colleagues identified insufficient medical and nursing coverage, inadequate communications, and visiting facilities for patient's families as the most significant problems facing the unit. The ICU patients in this study were on average 53 years of age with a mean length of stay of 12.9 hours. Seventy percent were mechanically ventilated, 77.8% required invasive monitoring, and 4.5% died in the PACU while awaiting placement in the ICU. The busiest hours of admission were 1 am to 11 am.[214]

In an effort to ensure the quality of patient care in the PACU, the professional societies responsible for the delivery of care in the unit have collaborated to develop standards for the care of ICU overflow patients. The "Joint Position Statement on ICU Overflow Patients" issued in 2000 is the result of this collaboration. It specifically requires that PACU staffing meet the nursing staffing ratios and competencies required in the critical care units.[215]

The Joint Position Statement reproduced here recommends that the following criteria be met:

- It must be recognized that the primary responsibility for Phase 1 PACU is to provide the optimal standard of care to the postanesthesia patient and to effectively maintain the surgery schedule.
- Appropriate staffing requirements should be met to maintain safe, competent nursing care of the postanesthesia patient as well as the ICU patient. Staffing criteria for the ICU patient should be consistent with ICU guidelines and based on individual acuity and needs.
- Phase 1 PACUs are by their nature critical care units and as such should meet the competencies required for the care of the critically ill patient. These competencies should include, but are not limited to, ventilator management, hemodynamic monitoring, and medication administration, as appropriate to their patient population.
- Management should develop and implement a comprehensive resource utilization plan with ongoing assessment that supports the staffing needs for both the PACU and ICU patients when the need for overflow admission arises.
- Management should have a multidisciplinary plan to address appropriate utilization of ICU beds. Admission and discharge criteria should be utilized to evaluate the necessity for critical care and to determine the priority of admission.

In addition to increasing the acuity of patient care in the PACU, the shortage of ICU beds has encouraged the de-escalation of care in selected patient populations. Postoperative patients who were historically admitted directly to the ICU from the operating room for intensive or specialized monitoring have had successful recovery by routine postoperative care in the PACU. Examples include postoperative craniotomy,[216] liver transplantation,[217,218] and cardiac surgery patients. The neurosurgical group at the University of Florida has shown that uncomplicated craniotomy patients can be safely cared for in the PACU at a significant savings of hospital-days and cost without increased morbidity or mortality.[187] Likewise, the trend to early extubation of liver transplant patients in the operating room has led to the successful uncomplicated recovery of these patients in the PACU. Finally, in an effort to protect ICU bed availability and reduce the number of cardiac surgery cancellations, a group in Melbourne established a cardiac surgery recovery unit within the PACU.[219] Each of these examples requires adequate space and specialized nursing skills to be successful.

OUTPATIENT PROCEDURES

Finally, the PACU has responded to the economic restrictions that currently limit hospital resources by accommodating the performance of simple outpatient procedures (see Chapter 72).[220] The PACU is uniquely equipped to care for patients who are undergoing noninvasive and minimally invasive procedures such as electroconvulsive therapy,[221,222] cardioversion,[223] epidural blood patch,[220] and liver biopsy.[220] Ambulatory patients undergoing such procedures can be admitted directly to the PACU for the procedure and discharged to home after a brief recovery period. In order to do so, the PACU must be appropriately staffed and scheduled so as to not interfere with routine operating room scheduling and postoperative recovery. Electroconvulsive therapy is somewhat unique in that it requires general anesthesia that is delivered by an anesthesia care practitioner. Typically these are short procedures that can be scheduled before the routine operating room cases. One successful electroconvulsive therapy program schedules the procedure at 5:30 am with nurse-to-patient ratio of 2:1 and estimated PACU length of stay of 2 hours.[222]

Summary

The PACU is more than a postanesthesia observation unit. It is unique in its ability to support the care of patients of all ages and in every stage of illness. Since its inception more than 50 years ago, the PACU has proved to be an exceptionally adaptable unit that is equipped to meet the demands of an evolving healthcare system.

Acknowledgment

The editors and publisher would like to thank Drs. Daniel Sessler, Theodora Katherine Nicholau, and Christian C. Apfel for their contributions in the prior edition of this work. Their chapters have served as the foundation for the current chapter.

Acute Postoperative Pain

ROBERT W. HURLEY, NABIL M. ELKASSABANY, and
CHRISTOPHER L. WU

KEY POINTS

- The process of nociception is a dynamic process (i.e., neuroplasticity) with multiple points of modulation. Persistent noxious input may result in relatively rapid neuronal sensitization and possibly persistent pain.
- Postoperative pain, especially when poorly controlled, results in harmful acute effects (i.e., adverse physiologic responses) and chronic effects (i.e., delayed long-term recovery and chronic pain).
- By preventing central sensitization, preventative analgesia may reduce acute and chronic pain. Although studies overwhelmingly support the concept of preemptive analgesia, the evidence from clinical trials is equivocal, mostly because of methodological issues.
- Multimodal analgesia entails use of multiple classes of analgesic drugs (acetaminophen, gabapentinoids, nonsteroidal antiinflammatory drugs [NSAIDs], ketamine, and others) to act on different receptors along the pain pathway. Different drugs act synergistically to enhance analgesia and reduce side effects resulting from use of an individual class of drugs. Use of multimodal analgesia is recommended whenever feasible.
- By allowing individual titration of analgesic drugs, use of patient-controlled analgesia (oral, subcutaneous, iontophoretic, intravenous, paravertebral, or epidural) may provide several advantages over traditional provider-administered analgesia (e.g., intramuscular or intermittent intravenous injections) in the management of postoperative pain.
- The incidence of respiratory depression from opioids is not significantly different among the various routes of administration (i.e., oral, intravenous vs. intramuscular vs. subcutaneous vs. neuraxial). Appropriate monitoring of patients receiving opioid analgesics is essential to detect those with opioid-related side effects, such as respiratory depression. When compared with systemic opioids, perioperative epidural analgesia may confer several advantages, including a facilitated return of gastrointestinal function and decrease in the incidence of pulmonary complications, coagulation-related adverse events and cardiovascular events, especially in higher-risk patients or procedures. However, the risks and benefits of epidural analgesia should be evaluated for each patient, and appropriate monitoring protocols should be used during postoperative epidural analgesia.
- Epidural analgesia is not a generic entity because different catheter locations (catheter-incision congruent vs. catheter-incision incongruent), durations of postoperative analgesia, and analgesic regimens (local anesthetics vs. opioids) may differentially affect perioperative morbidity.
- Postoperative pain management should be tailored to the needs of special populations (e.g., opioid-tolerant, pediatric, and obese patients, as well as those with obstructive sleep apnea) who may have different anatomic, physiologic, pharmacologic, or psychosocial issues.

Fundamental Considerations

A revolution in the management of acute postoperative pain has occurred during the past four decades. Widespread recognition of the undertreatment of acute pain by clinicians, economists, and health policy experts has led to the development of a national clinical practice guideline for management of acute pain by the Agency for Healthcare Quality and Research (formerly the Agency for Health Care Policy and Research) of the U.S. Department of Health and Human Services.[1] This landmark document includes acknowledgment of the historical inadequacies in perioperative pain management, importance of good pain control, need for accountability for adequate provision of perioperative analgesia by health care institutions, and a statement on the need for involvement of specialists in appropriate cases. In addition, several professional societies including American Society of Anesthesiologists (ASA),[2] The Joint Commission,[3] American Society of Regional Anesthesia and Pain Medicine, and American Pain Society[4] have developed clinical practice guidelines for acute pain management or provided new pain management standards. With their knowledge of and familiarity with pharmacology, various regional anesthetic techniques, and the neurobiology of nociception, anesthesiologists are prominently associated with the clinical and research advances in acute postoperative pain management. Anesthesiologists developed the concepts of acute pain services (APS) (inpatient pain services), application of evidence-based practice to acute postoperative pain, and creation of innovative approaches to acute pain medicine (APM), all of which are a natural extension of the anesthesiologist's role as a "perioperative physician," consultant, and therapist throughout the institution, in addition to being a highly skilled expert in the operating room. Provision of effective analgesia for surgical and other medical patients is an important component of this multidimensional role. An area that is often challenging in the acute perioperative pain services (PPS) is the management of patients with acute surgical pain in addition to a baseline chronic pain. These patients are often not well served by the arbitrary distinction of "acute" versus "chronic" pain services in hospitals. Anesthesiologists are well trained to manage acute pain in the patient with concomitant chronic pain as a result of the strength of chronic pain curricula in current anesthesiology training programs. Although this chapter focuses on the patient who has acute perioperative pain, acute management of chronic pain in the hospitalized setting is discussed in Chapter 51, "Management of the Patient with Chronic Pain."

PAIN PATHWAYS AND THE NEUROBIOLOGY OF NOCICEPTION

Surgery produces tissue injury with consequent release of histamine and inflammatory mediators such as peptides (e.g., bradykinin), lipids (e.g., prostaglandins), neurotransmitters (e.g., serotonin), and neurotrophins (e.g., nerve growth factor).[5] Release of inflammatory mediators activates peripheral nociceptors, which initiate transduction and transmission of nociceptive information to the central nervous system (CNS) and the process of neurogenic inflammation in which release of neurotransmitters (e.g., substance P and calcitonin gene-related peptide) in the periphery induces vasodilatation and plasma extravasation.[5] Noxious stimuli are transduced by peripheral nociceptors and transmitted by A-delta and C nerve fibers from peripheral visceral and somatic sites to the dorsal horn of the spinal cord, where integration of peripheral nociceptive and descending modulatory input (i.e., serotonin, norepinephrine, γ-aminobutyric acid, enkephalin) occurs. Further transmission of nociceptive information is determined by complex modulating influences in the spinal cord. Some impulses pass to the ventral and ventrolateral horns to initiate segmental (spinal) reflex responses, which may be associated with increased skeletal muscle tone, inhibition of phrenic nerve function, or even decreased gastrointestinal motility. Others are transmitted to higher centers through the spinothalamic and spinoreticular tracts, where they induce supra-segmental and cortical responses to ultimately produce the perception of and affective component of pain.

Continuous release of inflammatory mediators in the periphery sensitizes functional nociceptors and activates dormant ones. Sensitization of peripheral nociceptors may occur and is marked by a decreased threshold for activation, increased rate of discharge with activation, and increased rate of basal (spontaneous) discharge. Intense noxious input from the periphery may also result in central sensitization ("persistent postinjury changes in the CNS that result in pain hypersensitivity")[6] and hyperexcitability ("exaggerated and prolonged responsiveness of neurons to normal afferent input after tissue damage").[6] Such noxious input may lead to functional changes in the dorsal horn of the spinal cord and other consequences that may later cause postoperative pain to be perceived as more painful than it would otherwise have been. The neural circuitry in the dorsal horn is extremely complex, and we are just beginning to elucidate the specific role of the various neurotransmitters and receptors in the process of nociception.[5] However, it seems that certain receptors (e.g., *N*-methyl-D-aspartate [NMDA]) may be especially important for the development of chronic pain after an acute injury, although other neurotransmitters or second messenger effectors (e.g., substance P, protein kinase C) may also play important roles in spinal cord sensitization and chronic pain. Our understanding of the neurobiology of nociception has progressed from the hard-wired system proposed by Descartes in the 17th century to the current view of neuroplasticity in which dynamic integration and modulation of nociceptive transmission take place at several levels. There still are many gaps in our knowledge of the specific roles of various receptors, neurotransmitters, and molecular structures in the process of nociception.

An understanding of the neurobiology of nociception is important for appreciating the transition from acute to chronic pain. The traditional dichotomy between acute and chronic pain is arbitrary because acute pain may quickly transition into chronic pain.[7] Noxious stimuli can produce expression of new genes (which are the basis for neuronal sensitization) in the dorsal horn of the spinal cord within 1 hour and these changes are sufficient to alter behavior within the same timeframe.[8] Also, the intensity of acute postoperative pain is a significant predictor of chronic postoperative pain.[9] Control of perioperative pain (e.g., preventive analgesia) and the manner in which it is implemented (e.g., multimodal perioperative pain management) may be important in facilitating short- and long-term patient convalescence after surgery.

ACUTE AND CHRONIC EFFECTS OF POSTOPERATIVE PAIN

Uncontrolled postoperative pain may produce a range of detrimental acute and chronic effects. The attenuation of perioperative pathophysiology that occurs during surgery through reduction of nociceptive input to the CNS and optimization of perioperative analgesia may decrease complications and facilitate recovery during the immediate postoperative period[10] and after discharge from the hospital.

Acute Effects

The perioperative period has a variety of pathophysiologic responses that may be initiated or maintained by nociceptive input. At one time, these responses may have had a beneficial teleological purpose; however, the same response to the iatrogenic nature of modern-day surgery may be harmful. Uncontrolled perioperative pain may enhance some of these perioperative pathophysiologies and increase patient morbidity and mortality. Attenuation of postoperative pain, especially with certain types of analgesic regimens, may decrease perioperative morbidity and mortality.

Transmission of nociceptive stimuli from the periphery to the CNS results in the neuroendocrine stress response, a combination of local inflammatory substances (e.g., cytokines, prostaglandins, leukotrienes, tumor necrosis factor-α) and systemic mediators of the neuroendocrine response. The dominant neuroendocrine responses to pain involve hypothalamic-pituitary-adrenocortical and sympathoadrenal interactions. Suprasegmental reflex responses to pain result in increased sympathetic tone, increased catecholamine and catabolic hormone secretion (e.g., cortisol, adrenocorticotropic hormone, antidiuretic hormone, glucagon, aldosterone, renin, angiotensin II), and decreased secretion of anabolic hormones.[11] The effects include sodium and water retention and increased levels of blood glucose, free fatty acids, ketone bodies, and lactate. A hypermetabolic, catabolic state occurs as metabolism and oxygen consumption are increased and metabolic substrates are mobilized from storage depots.[11] The extent of the stress response is influenced by many factors, including the type of anesthesia and intensity of the surgical injury, with the extent of the stress response being proportional to the degree of surgical trauma.[12] The negative nitrogen balance and protein catabolism may impede convalescence; however, attenuation of the stress response and postoperative pain may facilitate and accelerate the patient's recovery postoperatively.

The neuroendocrine stress response may enhance detrimental physiologic effects in other areas of the body. The stress response is likely a factor in the postoperative development of hypercoagulability. Enhancement of coagulation (i.e., decreased levels of natural anticoagulants and increased levels of procoagulants), inhibition of fibrinolysis, and increased platelet reactivity and plasma viscosity may enhance the incidence of postoperative hypercoagulable-related events such as deep venous thrombosis, vascular graft failure, and myocardial ischemia.[13] The stress response may also enhance postoperative immunosuppression, the extent of which correlates with the severity of surgical injury.[7] Hyperglycemia from the stress response may contribute to poor wound healing and depression of immune function.

Uncontrolled postoperative pain may activate the sympathetic nervous system and thereby contribute to morbidity or mortality. Sympathetic activation may increase myocardial oxygen consumption, which may be important in the development of myocardial ischemia and infarction,[13] and may decrease myocardial oxygen supply through coronary vasoconstriction and attenuation of local metabolic coronary vasodilation.[14] Activation of the sympathetic nervous system may also delay return of postoperative gastrointestinal motility, which may develop into paralytic ileus. Although postoperative ileus is the result of a combination of inhibitory input from central and local factors,[13,14] an increase in sympathetic efferent activity, such as from uncontrolled pain, may decrease gastrointestinal activity and delay return of gastrointestinal function.

Nociceptors are activated after surgical trauma and may initiate several detrimental spinal reflex arcs. Postoperative respiratory function is markedly decreased, especially after upper abdominal and thoracic surgery. Spinal reflex inhibition of phrenic nerve activity is an important component of this decreased postoperative pulmonary function.[13] However, patients with poor postoperative pain control may breathe less deeply, have an inadequate cough, and be more susceptible to the development of postoperative pulmonary complications.[14] Activation of nociceptors may also initiate spinal reflex inhibition of gastrointestinal tract function and delay return of gastrointestinal motility.[13]

Many detrimental postoperative pathophysiologic effects can occur in the perioperative period and can activate nociceptors and the stress response. Uncontrolled pain may activate the sympathetic nervous system, which can cause a variety of potentially harmful physiologic responses that may adversely increase morbidity and mortality. Nociceptor activation may also result in several detrimental inhibitory spinal reflexes. Control of the pathophysiologic processes associated with acute postoperative pain may attenuate the stress response, sympathetic outflow, and inhibitory spinal reflexes and contribute to improvements in morbidity, mortality, and patient-reported outcomes (e.g., health-related quality of life [HRQL], patient satisfaction).[13]

Chronic Effects

Chronic persistent postsurgical pain (CPSP) is a largely unrecognized problem that may occur in 10% to 65% of postoperative patients (depending on the type of surgery), with 2% to 10% of these patients experiencing severe CPSP.[15] Poorly controlled acute postoperative pain is an important predictive factor in the development of CPSP.[9,16] The transition from acute to chronic pain occurs very quickly, and long-term behavioral and neurobiologic changes occur much sooner than was previously thought.[7] CPSP is relatively common after procedures such as limb amputation (30%-83%), thoracotomy (22%-67%), sternotomy (27%), breast surgery (11%-57%), and gallbladder surgery (up to 56%).[9] Although the severity of acute postoperative pain may be an important predictor in the development of CPSP,[9] a causal relationship has not been definitively established, and other factors (e.g., area of postoperative hyperalgesia) may be more important in predicting the development of CPSP.[17] One such factor may be the severity of the patient's preoperative pain. Patients with more intense levels of preoperative pain may also develop a degree of CNS sensitization predisposing them to the increased likelihood of higher postoperative pain and the subsequent development of chronic pain.[17] Thus, it is important that APS clinicians understand chronic pain conditions and involve themselves in the patient's preoperative care. The increased involvement of the APM team in preoperative anesthesia clinics or services can positively attenuate the incidence and severity of postoperative pain.

Control of acute postoperative pain may improve long-term recovery or patient-reported outcomes (e.g., quality of life). Patients whose pain is controlled in the early postoperative period (especially with the use of continuous epidural or peripheral catheter techniques) may be able to actively participate in postoperative rehabilitation, which may improve short- and long-term recovery after surgery.[18] Optimizing treatment of acute postoperative pain can improve HRQL.[19] Postoperative chronic pain that develops as a result of poor postoperative pain control may interfere with patients' activities of daily living.

Preventive Analgesia

The older terminology of "preemptive" analgesia referred to an analgesic intervention that preceded a surgical injury and was more effective in relieving acute postoperative pain than the same treatment following surgery. The precise definition of preemptive analgesia is one of the major controversies in this area of medicine and contributes to the question of whether preemptive analgesia is clinically relevant. Definitions of preemptive analgesia include what is administered before the surgical incision, what prevents the establishment of central sensitization resulting from incisional injury only (i.e., intraoperative period), what prevents central sensitization resulting from incisional and inflammatory injury (i.e., intraoperative and postoperative periods), or the entire perioperative period encompassing preoperative interventions, intraoperative analgesia, and postoperative pain management (i.e., preventive analgesia).[6] The first two definitions are relatively narrow and may contribute to the lack of a detectable effect of preemptive analgesia in clinical trials. The rationale for preemptive analgesia was based on the inhibition of the development of central sensitization. Effectively, noxious input initiated by surgical procedures induced a state of CNS hyperactivity that accentuates pain. Although a very popular and discussed theory, a single analgesic treatment (either peripheral or neuraxial) before the incision does not reduce postoperative pain behaviors beyond the expected duration of the analgesic effect.[20] When the block of nociceptive afferents diminishes, the surgical injury is able to reinitiate central sensitization. Clinical trials have been negative.[21] For these reasons, this terminology has fallen out of favor.

As stated previously, intense noxious input (e.g., postoperative pain from the periphery) can change the CNS (i.e., central sensitization) to induce “pain hypersensitivity” and hyperexcitability (i.e., exaggerated and prolonged responsiveness of neurons to normal afferent input after tissue damage). Preventive analgesia is aimed at inhibiting the development of this type of chronic pain. This definition broadly includes any regimen given at any time during the perioperative period that controls pain-induced sensitization. Central sensitization and hyperexcitability can develop after the surgical incision in a patient who has no history of preoperative pain.

In contrast, some patients may already have existing acute or chronic pain and developed central sensitization prior to the surgical incision. These patients with preexisting pain may have even more intense pain in the postoperative period. This augmentation of preexisting pain can occur in the acutely hospitalized and even in those patients in subacute or chronic outpatient settings. Preventing the establishment of altered central processing by analgesic treatment may result in short-term (e.g., reduction in postoperative pain and accelerated recovery) and long-term (e.g., reduction in chronic pain and improvement in HRQL[19] benefits during a patient’s convalescence). Unfortunately, many clinical studies (e.g., trials) lack clarity of study design and clear terminology of preemptive versus preventative analgesia.[21,22]

Timing of the intervention may not be as clinically important as other aspects of preventive analgesia (i.e., intensity and duration of the intervention). An intervention administered before the surgical incision is not preventative if it is incomplete or insufficient such that central sensitization is not prevented. Incisional and inflammatory injuries are important in initiating and maintaining central sensitization. Confining the definition of preventative analgesia to only the intraoperative (incisional) period is not relevant or appropriate because the inflammatory response lasts well into the postoperative period and continues to maintain central sensitization.

Maximal clinical benefit is observed when there is complete multi-segmental blockade of noxious stimuli with extension of this into the postoperative period. Preventing central sensitization with intensive multimodal analgesic interventions[21] could theoretically reduce the intensity or even eliminate acute postoperative pain/hyperalgesia and chronic pain after surgery.[9]

Multimodal Approach to Perioperative Recovery/Enhanced Recovery after Surgery

The analgesic benefits of controlling postoperative pain are generally maximized when a multimodal strategy to facilitate the patient’s convalescence is implemented. Yet, postoperative pain treatment may not provide major improvements in some outcomes because it is unlikely that a unimodal intervention can be effective in addressing a complex problem such as perioperative outcomes.[10,23] The complex nature of nociception and mixed mechanisms of generating surgical pain are also responsible for failure of unimodal analgesia to adequately address postoperative pain.[10,23] Principles of a multimodal analgesia include using multiple strategies and drug classes to manage patient expectation and control postoperative pain to allow early mobilization, enteral nutrition, and to attenuate the perioperative stress response.[10] These strategies include: patient education, local anesthetic-based techniques (local infiltration, peripheral nerve blocks, and neuraxial analgesia),[10] and a combination of analgesic drugs that act via different mechanisms on different receptors within the pain transmission pathway to provide synergistic effect, superior analgesia, and physiologic benefits.

A multimodal approach to perioperative recovery to control postoperative pathophysiology and facilitate rehabilitation is an integral part of almost all enhanced recovery after surgery (ERAS) pathways and will result in accelerated recovery and decreased length of hospitalization.[24] One of the key components of a multimodal analgesic regimen within any ERAS pathway is the minimization of opioid use and side effects from opioids by utilizing nonopioid analgesics and techniques.[25] Patients undergoing major abdominal or thoracic procedures and who participate in a multimodal strategy have a reduction in hormonal and metabolic stress, preservation of total-body protein, shorter times to tracheal extubation, lower pain scores, earlier return of bowel function, and earlier fulfillment of intensive care unit discharge criteria when compared to patients receiving traditional pain management.[24] ERAS pathways integrate the most recent evidence from surgery, anesthesiology, nociceptive neurobiology, and pain treatment, and transforms traditional care programs into effective postoperative rehabilitation pathways.[24] This approach will decrease perioperative morbidity, costs of care, decrease the length of hospital stay, and improve patient satisfaction without compromising safety.[26,27] ERAS pathways are more common in adult surgical patients, although there is increasing interest in utilizing ERAS in pediatric patients.[26] Widespread implementation of these programs requires multidisciplinary collaboration, change in the traditional principles of postoperative care, additional resources, and expansion of the traditional APS, which may be limited in the current economic climate.[28]

Treatment Methods

Many options are available for the treatment of postoperative pain, including systemic (i.e., opioid and non-opioid) analgesics and regional (i.e., neuraxial and peripheral) analgesic techniques. By considering patients' preferences and making an individualized assessment of the risks and benefits of each treatment modality, the clinician can optimize the postoperative analgesic regimen for each patient. Essential aspects of postoperative monitoring of patients receiving various postoperative analgesic treatment methods are listed in Box 81.1.[29]

BOX 81.1 Monitoring and Documentation of Postoperative Analgesia

Analgesic Medication*

Medication, concentration, and dose of drug
Settings of PCA device: demand dose, lockout interval, continuous basal infusion
Amount of drug administered (including number of unsuccessful and successful doses)
Limits set (e.g., 1- and 4-h limits on dose administered)
Supplemental or breakthrough analgesics

Routine Monitoring

Vital signs: temperature, heart rate, blood pressure, respiratory rate, average pain score
Pain score at rest and with activity, pain relief

Side Effects

Cardiovascular: hypotension, bradycardia, or tachycardia
Respiratory status: respiratory rate, level of sedation
Nausea and vomiting, pruritus, urinary retention

Neurologic Examination

Assessment of motor block or function and sensory level
Evidence of epidural hematoma

Instructions Provided

Treatment of side effects
Concurrent use of other CNS depressants
Parameters for triggering notification of the covering physician
Provision of contact information (24 hr/7 day per week) if problems occur
Emergency analgesic treatment if the PCA device fails

*Postoperative analgesia includes systemic opioids and regional analgesic techniques. This list incorporates some of the important elements of preprinted orders, documentation, and intravenous PCA and epidural analgesia daily care described in the ASA Practice Guidelines for Acute Pain Management.[29]

CNS, Central nervous system; *PCA*, patient-controlled analgesia.

Systemic Analgesic Techniques

OPIOIDS

Advantages and Characteristics

Opioid analgesics are one of the cornerstone options for the treatment of postoperative pain. They generally exert their analgesic effects through μ-receptors in the CNS, although opioids may also act at peripheral opioid receptors. A theoretical advantage of opioid analgesics is that there is no analgesic ceiling. Realistically, the analgesic efficacy of opioids is typically limited by the development of tolerance or opioid-related side effects such as nausea, vomiting, sedation, or respiratory depression. Opioids may be administered by the subcutaneous, transcutaneous, transmucosal, or intramuscular route, but the most common routes of postoperative systemic opioid analgesic administration are oral and intravenous (IV). Opioids may also be administered at specific anatomic sites such as the intrathecal or epidural space (see later sections, "Single-Dose Neuraxial Opioids" and "Continuous Epidural Analgesia").

There is wide intersubject and intrasubject variability in the relationship of opioid dose, serum concentration, and analgesic response in the treatment of postoperative pain. Serum drug concentrations may exhibit wider variability with certain routes of administration (e.g., intramuscular) than with others (e.g., IV). In general, opioids are administered parenterally (intravenously or intramuscularly) for the treatment of moderate to severe postoperative pain, in part because these routes provide a more rapid and reliable onset of analgesic action than the oral route does. Parenteral opioid administration may be necessary in patients who are unable to tolerate oral intake postoperatively. The transition from parenteral to oral administration of opioids usually occurs after the patient resumes oral intake and postoperative pain has been stabilized with parenteral opioids.

Intravenous Patient-Controlled Analgesia

Various factors, including the aforementioned broad interpatient and intrapatient variability in analgesic needs, variability in serum drug levels (especially with intramuscular injection), and administrative delays, may contribute to inadequate postoperative analgesia. A traditional prescribed as-needed (PRN) analgesic regimen probably cannot compensate for these limitations. By circumventing some of these issues, IV patient-controlled analgesia (PCA) optimizes delivery of analgesic opioids and minimizes the effects of pharmacokinetic and pharmacodynamic variability in individual patients. IV PCA is based on the premise that a negative-feedback loop exists; when pain is experienced, analgesic medication is self-administered, and when pain is reduced, there are no further demands. When the negative-feedback loop is violated, excessive sedation or respiratory depression may occur. Although some equipment-related malfunctions can occur, the PCA device itself is relatively free of problems, and most problems related to PCA use result from user or operator error.[30]

A PCA device can be programmed for several variables, including the demand (bolus) dose, lockout interval, and background infusion (Table 81.1). An optimal demand or bolus dose is integral to the efficacy of IV PCA because an insufficient demand dose may result in inadequate analgesia, whereas an excessive demand dose may result in a higher incidence of undesirable side effects such as respiratory depression.[31] Although the optimal demand dose is uncertain, the data available suggest that the optimal

TABLE 81.1 Intravenous Patient-Controlled Analgesia Regimens

Drug Concentration	Size of Bolus*	Lockout Interval (min)	Continuous Infusion
AGONISTS			
Morphine (1 mg/mL)			
Adult	0.5-2.5 mg	5-10	—
Pediatric	0.01-0.03 mg/kg (max, 0.15 mg/kg/h)	5-10	0.01-0.03 mg/kg/h
Fentanyl (0.01 mg/mL)

Nalbuphine (1 mg/mL)	1-5 mg	5-15	—
Pentazocine (10 mg/mL)	5-30 mg	5-15	—

*All doses are for adult patients unless noted otherwise. Units vary across agents for size of the bolus (mg vs. mg/kg vs. mcg vs. μg/kg) and continuous infusion (mg/kg/h vs. μχg/kg/h). The anesthesiologist should proceed with titrated intravenous loading doses if necessary to establish initial analgesia. Individual patient requirements vary widely, with smaller doses typically given to elderly or compromised patients. Continuous infusions are not initially recommended for opioid-naïve adult patients.

demand dose is 1 mg for morphine and 40 μg for fentanyl in opioid-naïve patients; however, the actual dose for fentanyl (10-20 μg) is often less in clinical practice.[30] The lockout interval may also affect the analgesic efficacy of IV PCA. A lockout interval that is too long may result in inadequate analgesia and decrease the effectiveness of IV PCA. A lockout interval that is too short allows the patient to self-administer another demand dose before feeling the full analgesic effect of the previous dose and thus may contribute to an increase in medication-related side effects. In essence, the lockout interval is a safety feature of IV PCA, and although the optimal lockout interval is unknown, most intervals range from 5 to 10 minutes, depending on the medication in the PCA pump; varying the interval within this range appears to have no effect on analgesia or side effects.[30]

Most PCA devices allow administration of a continuous or background infusion in addition to the demand dose. Initially, routine use of a background infusion predicted certain advantages, including improved analgesia, especially during sleep; however, analgesic benefits of a background infusion have not been successful in opioid-naïve patients. A background infusion only increases the analgesic dosage used and the incidence of adverse respiratory events in the postoperative period, especially in adult subjects. Furthermore, use of a nighttime background infusion does not improve postoperative sleep patterns, analgesia, or recovery profiles.[32] Although routine use of continuous or background infusion as part of IV PCA in adult opioid-naïve patients is not recommended, a background infusion in opioid-tolerant or pediatric patients may be effective (see later sections, "Opioid-Tolerant Patients" and "Pediatric Patients") (also see Chapter 24).

When compared with traditional PRN analgesic regimens, IV PCA provides superior postoperative analgesia and improves patient satisfaction, but the presence of economic benefits is not clear.[33] A metaanalysis revealed that IV PCA (vs. as-needed opioids) provides significantly better analgesia and patient satisfaction; however, these patients used more opioids and had a more frequent incidence of pruritus than those treated with PRN opioids, but there was no difference in the incidence of adverse events.[33] With regard to economic outcomes, whether IV PCA is less expensive than traditional PRN intramuscular opioid administration is not clear because the calculations of cost are complex.

IV PCA may provide advantages when assessing other patient-related outcomes such as patient satisfaction; these outcomes have become more important as healthcare organizations use them as a measure of quality and a tool for marketing purposes. Patients usually prefer IV PCA over intravenously, intramuscularly, or subcutaneously administered PRN opioids. Greater patient satisfaction with IV PCA may be the result of superior analgesia and perceived control over the administration of analgesic medications and avoidance of disclosing pain or securing analgesic medication from nurses; however, the reasons for patient satisfaction are complex and many factors may contribute to or predict satisfaction with IV PCA. Although IV PCA use overall creates better satisfaction, the proper assessment of patient satisfaction can be complex.[34]

The incidence of opioid-related adverse events from IV PCA is not different from that of PRN opioids administered intravenously, intramuscularly, or subcutaneously. The rate of respiratory depression associated with IV PCA is infrequent (approximately 1.5%) and is not more frequent than that with PRN systemic or neuraxial opioids.[35] Factors that may influence the frequency and intensity of respiratory depression with IV PCA include use of a background infusion, advanced age, concomitant administration of sedative or hypnotic drugs, and coexisting pulmonary disease such as obstructive sleep apnea (OSA).[36] IV PCA-related respiratory depression may also be caused by errors in programming or administration (i.e., operator error).[37]

NON-OPIOIDS

Nonsteroidal Antiinflammatory Agents

Nonsteroidal antiinflammatory drugs (NSAIDs) consist of a diverse group of analgesic compounds with different pharmacokinetic properties. The primary mechanism by which NSAIDs exert their analgesic effect is through inhibition of cyclooxygenase (COX) and synthesis of prostaglandins, which are important mediators of peripheral sensitization and hyperalgesia. In addition to being peripherally acting analgesics, NSAIDs can also exert their analgesic effects through inhibition of spinal COX.[38] The discovery of at least two COX isoforms (i.e., COX-1 is constitutive and COX-2 is inducible) with different functions (i.e., COX-1 participates in platelet aggregation, hemostasis, and gastric mucosal protection, whereas COX-2 participates in pain, inflammation, and fever) has led to the development of selective COX-2 inhibitors that differ from traditional NSAIDs, which block both COX-1 and COX-2.[39] The discovery of a COX-3 variant may represent a primary central mechanism by which acetaminophen and other antipyretics decrease pain and fever; however, the precise relationship between COX-3 and acetaminophen is still uncertain.[40]

NSAIDs given alone generally provide effective analgesia for mild to moderate pain. NSAIDs are also traditionally considered a useful adjunct to opioids for the treatment of moderate to severe pain. Yet, some quantitative, systematic reviews suggest that NSAIDs, alone or in combination with opioids, may be more beneficial than previously thought (Table 81.2 and Fig. 81.1). NSAIDs may be administered orally or parenterally and are particularly useful as components of a multimodal analgesic regimen by producing analgesia through a different mechanism from that of opioids or local anesthetics. Several meta-analyses have examined the analgesic efficacy of NSAIDs (including COX-2 inhibitors) and acetaminophen when added to IV PCA with opioids. Surprisingly and importantly, NSAIDs[41,42] resulted in a statistically significant (but probably not clinically meaningful) reduction in pain scores.[43,44] Although all regimens significantly decreased morphine consumption, only NSAIDs reduced risk for the opioid-related side effects of nausea, vomiting, and sedation.

Perioperative use of NSAIDs has several side effects, including decreased hemostasis, renal dysfunction, and gastrointestinal hemorrhage. Inhibition of COX and the formation of prostaglandins cause many of the side effects, which mediate many diverse processes throughout the body. Decreased hemostasis from NSAID use is from platelet dysfunction and inhibition of thromboxane A2 (generated by COX-1), an important mediator of platelet aggregation and vasoconstriction. Evidence of the effect of NSAIDs on perioperative bleeding is equivocal; a surveillance study of perioperative ketorolac administration did not demonstrate a significant increase in operative site bleeding. Whether NSAIDs may also have a deleterious effect on bone healing and osteogenesis is controversial. Although NSAIDs have been used following acetabular/hip fractures and hip replacement surgery to reduce heterotopic ossification, the short-term effect of NSAIDs on other skeletal tissues is less clear.[45] Two recent systematic reviews indicated that when examining the highest-quality studies, there was no increased risk of nonunion with NSAID exposure. Certainly, a short-term NSAID regimen can be used for treatment of post-fracture pain without significantly increasing the risk of disrupted healing.[46] A brief (<14 days) exposure to normal-dose NSAIDs (e.g., ketorolac <120 mg/day) was safe after spinal fusion; however, use of large-dose ketorolac

TABLE 81.2 Relative Efficacy of Single-Dose Analgesics in Providing Greater than 50% Relief of Moderate to Severe Postoperative Pain

Drug*	Mean NNT†	95% CI
Acetaminophen (1000 mg PO)	3.8	3.4-4.4
Aspirin (600-650 mg PO)	4.4	4.0-4.9
Aspirin (1000 mg PO)	4.0	3.2-5.4
Diclofenac (50 mg PO)	2.3	2.0-2.7
Diclofenac (100 mg PO)	1.9	1.6-2.2
Ibuprofen (600 mg PO)	2.4	1.9-3.3
Ketorolac (10 mg PO)	2.6	2.3-3.1
Ketorolac (30 mg IM)	3.4	2.5-4.9
Naproxen (550 mg PO)	2.7	2.3-3.3
Celebrex (200 mg PO)	3.5	2.9-4.4
Celebrex (400mg PO)	2.1	1.8-2.5
Tramadol (100 mg PO)	4.8	3.8-6.1
Gabapentin (600 mg PO)	11	6.0-35
Codeine (60 mg) + acetaminophen (600-650 mg PO)	4.2	3.4-5.3
Oxycodone (5 mg) + acetaminophen (325 mg PO)	2.5	2.0-3.2
Codeine (60 mg PO)	16.7	11.0-48.0
Morphine (10 mg IM)	2.9	2.6-3.6
Oxycodone (15 mg PO)	2.4	1.5-4.9

†NNT in this case refers to the number of patients who must be treated to obtain greater than 50% relief of moderate to severe postoperative pain. NNT conveys statistical and clinical significance, is useful in comparing the efficacy of different interventions, and summarizes treatment effects in a clinically relevant manner. A lower mean NNT implies greater analgesic efficacy in this example. *CI*, confidence interval; *IM*, intramuscular; *NNT*, number needed to treat; *PO*, oral route.

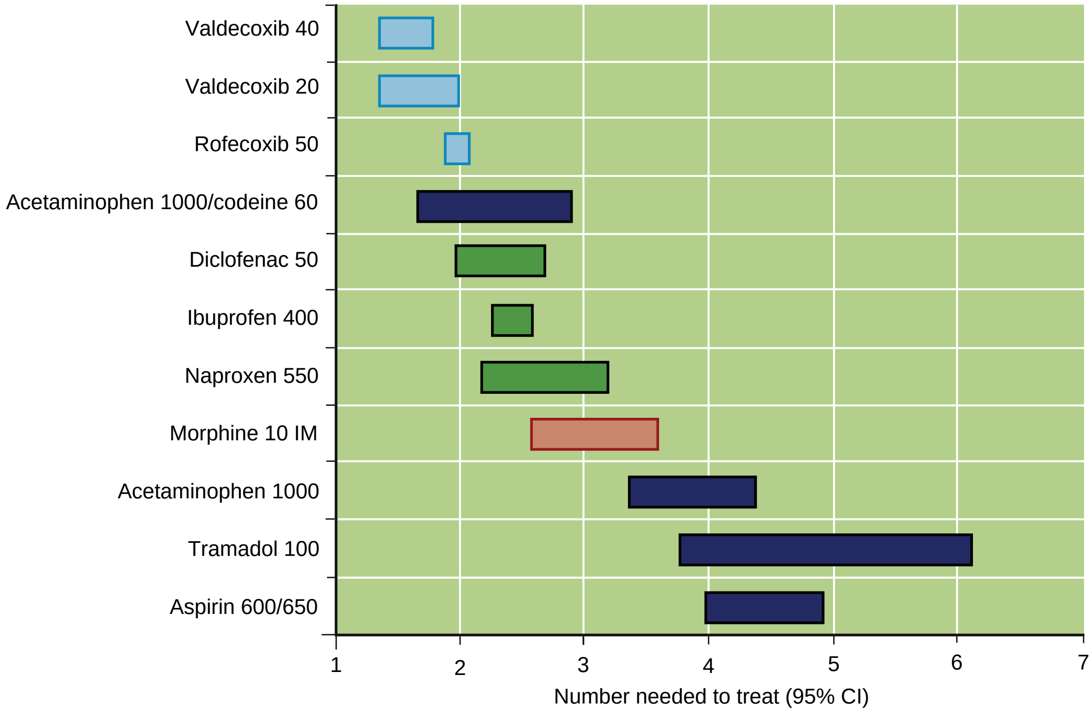

Fig. 81.1 Number needed to treat (NNT) for at least 50% pain relief in patients with moderate to severe pain. The mean and 95% confidence interval *(CI)* for the NNTs are shown for several opioid and nonopioid analgesics from Table 81.2. The NNTs are derived from trials investigating the efficacy of a single dose of nonopioid analgesic versus placebo in providing more than 50% pain relief for moderate to severe postoperative pain. Numbers with drug names are doses in mg. (From Bandolier. http://www.medicine.ox.ac.uk/bandolier/.)

(>120 mg/day) increased the risk of nonunion, suggesting a dose-dependent effect of perioperative NSAIDs on spinal fusion healing.[47] Spine surgeons will more commonly err on the conservative side and refuse to have postoperative spine fusion patients receive NSAIDs.

Perioperative NSAID-induced renal dysfunction may occur in high-risk patients, such as those with hypovolemia, abnormal renal function, or abnormal serum electrolytes, because prostaglandins dilate the renal vascular beds and mediate diuretic and natriuretic renal effects. NSAIDs should not be withheld in patients with normal preoperative renal function, as euvolemic patients with normal renal function are unlikely to be affected, although NSAIDs may cause a clinically unimportant transient reduction in renal function in the early postoperative period in patients with normal preoperative renal function.[48] Gastrointestinal bleeding may be more likely with NSAID intake because of inhibition of COX-1, which is required for the synthesis of cytoprotective gastric mucosal prostaglandins. Bronchospasm may be induced by NSAIDs (including aspirin).[49] Because expression of peripheral COX-2 is increased during inflammation, selective inhibition of COX-2 could theoretically provide analgesia without the side effects associated with COX-1 inhibition. COX-2 inhibitors have a less frequent incidence of gastrointestinal complications[50] and exhibit minimal platelet inhibition, even when administered in supratherapeutic doses.[51] However, long-term use of COX-2 inhibitors has an excess cardiovascular risk such that rofecoxib was withdrawn from the market.[52] The cardiovascular risks of COX-2 inhibitors are heterogeneous and influenced by many factors such as the specific medication, dosage, and patient characteristics.[52] Issues surrounding the perioperative use of COX-2 inhibitors are slightly different from those of longer-term use of COX-2 inhibitors. The perioperative use of potent COX-2 inhibitors resulted in a higher rate of cardiovascular events in high-risk (coronary artery bypass grafting)[53] but not lower-risk (major noncardiac surgery) patients. Celecoxib, a COX-2 inhibitor, has less COX-2 selectivity than other more potent COX-2 inhibitors (rofecoxib) and is still clinically available.[54] Nissen and associates conducted a randomized controlled trial (RCT) of 24,081 patients randomly assigned to celecoxib, naproxen, or ibuprofen and found that celecoxib was noninferior to ibuprofen or naproxen with regard to cardiovascular safety.[55] Liu and associates studied 10,873 patients admitted for total joint arthroplasty and concluded that perioperative use of NSAIDs was not associated with increased risk of postoperative myocardial ischemia and may reduce the hospital length of stay.[55,56]

Another controversial topic regarding NSAIDs is the association with postoperative bleeding. It is not surprising that several metaanalyses indicate that COX-2 inhibitors, which exhibit minimal platelet inhibition even when administered in supratherapeutic doses, are not associated with an increase in perioperative bleeding.[57-59] More recent metaanalyses also indicate that traditional NSAIDs (ibuprofen, ketorolac) are not associated with an increase in perioperative bleeding. Finally, some studies have been published suggesting a link between NSAIDs and anastomotic leak, but most studies are flawed or have preexisting selection bias and a metaanalysis did not demonstrate a statistically significant increase in incidence of anastomotic dehiscence with NSAIDs. Newer formulations of NSAIDs are approved for treatment of acute postoperative pain (IV ibuprofen,[60] and intranasal ketorolac[3]). Cost of the new drugs remains to be an issue, especially in today's cost-conscious healthcare environment.[61,62]

Acetaminophen

Acetaminophen has been used for several decades and is believed to have a central role of action in analgesia. It has antipyretic and antiinflammatory properties. Its mechanism of action is through activation of descending serotonergic pathways in the CNS and via the inhibition of prostaglandin synthesis.[63] It is used most often in conjunction with other medications as part of a multimodal analgesia protocol. Maximum recommended dose is 4 gm/day in adult patients. The US Food and Drug Administration (FDA) approved IV acetaminophen formulation for use in the United States in 2011.[64] Sinatra and colleagues studied the efficacy of IV acetaminophen after joint arthroplasty in a placebo-controlled study.[65] The study group had decreased pain scores, used fewer opioids, had a longer median time to morphine rescue compared to placebo, and were more satisfied with pain management. A metaanalysis of 865 patients enrolled in four clinical trials addressing the impact of addition of IV acetaminophen to multimodal analgesia after total hip and knee arthroplasty concluded that there was a significant decrease in pain score and opioid consumption on POD 1 to 3. Nausea and vomiting were decreased in the groups who received acetaminophen.[66] However, the quality of the studies included in the analysis was questioned. Peak plasma concentration is achieved faster after IV versus oral administration of acetaminophen.[67] Evidence to support the premise that increased bioavailability would enhance clinical efficacy is lacking. Cost effectiveness of the IV formulation and patient ability to tolerate oral intake, based on the targeted surgery, should be accounted for when considering integrating IV acetaminophen into a multimodal analgesia protocol. Data from 2013 show that the average increase in cost to hospitals adopting IV acetaminophen can be significant, based on its use.[68]

Gabapentinoids

Gabapentin and pregabalin, antiepileptic drugs also used in the treatment of neuropathic pain, interact with calcium channel α_2-delta ligands to inhibit calcium influx and subsequent release of excitatory neurotransmitters. However, oral pregabalin is absorbed more rapidly and has more absolute bioavailability (≥90% vs. <60%) than gabapentin.[69] Despite these differences, oral gabapentin improves the analgesic efficacy of opioids both at rest and with movement, and reduces opioid consumption and opioid-related side effects, but with a possibly increased incidence of side effects such as sedation and dizziness.[70-72] A metaanalysis investigating the analgesic efficacy of pregabalin for acute postoperative pain demonstrated use of pregabalin was associated with a decrease in opioid consumption and opioid-related side effects, but no difference in pain intensity.[73] Another meta-analysis suggested that perioperative administration of pregabalin may provide additional analgesia in the short term but also results in an increase in side effects such as dizziness/light-headedness or visual disturbances.[74]

Although gabapentinoids are commonly used as part of a multimodal analgesic regimen, it should be noted that there have been recent publications questioning the analgesic benefits of gabapentinoids.[75] Several studies have noted that the quality of evidence for a clinically relevant benefit of gabapentinoids is low and the serious adverse events in available trials were poorly reported.[76-78] When examining trials with low risk of bias, gabapentinoids may actually have a minimal opioid-sparing effect but the risk of serious adverse events seems increased, as the use of gabapentin is associated with increased rates of respiratory depression among patients undergoing laparoscopic surgery.[79] Finally, gabapentinoids may not provide any additional analgesia for some surgical procedures including total hip arthroplasty.[80] The use of gabapentinoids should be considered on an individual basis after surgery.

KETAMINE

Ketamine is traditionally recognized as an intraoperatively administered anesthetic; however, small subanesthetic dose (analgesic) ketamine can facilitate postoperative analgesia because of its NMDA-antagonistic properties, which may be important in attenuating central sensitization and opioid tolerance.[81] Ketamine can be administered orally, intravenously (PCA or as a continuous infusion), subcutaneously, or intramuscularly. A systematic review of perioperative ketamine use found that perioperative analgesic doses of ketamine reduce rescue analgesic requirements and pain intensity.[82] In addition, perioperative ketamine reduced 24-hour PCA morphine consumption and postoperative nausea or vomiting and had minimal adverse effects.[82] A subsequent systematic review found that IV ketamine for postoperative analgesia was an effective adjunct for postoperative analgesia, particularly in patients undergoing painful procedures such as upper abdominal, thoracic, and major orthopedic surgeries.[83] The administration of ketamine in postoperative pediatric patients is also associated with decreased postoperative pain intensity.[84] One potential concern is the possible impact of ketamine's amnestic effects on the neuropharmacologic and cognitive level of patients with use of perioperative ketamine infusions.[85] Although possible, these effects infrequently occur when the medication is given in analgesic doses. Ketamine has also been given epidurally and intrathecally, but racemic mixtures of ketamine are neurotoxic, and therefore the use of neuraxial racemic ketamine is strongly discouraged. Although further studies are needed to elucidate the specific parameters (e.g., dose, duration of use) for ketamine in the perioperative period, this analgesic can be considered on an individual basis as part of a multimodal approach to postoperative analgesia.

Tramadol

Tramadol is a synthetic opioid that exhibits weak μ-agonist activity and inhibits reuptake of serotonin and norepinephrine, although the relative degree of contribution of each modality to postoperative analgesia is not certain.[86] Although tramadol exerts its analgesic effects primarily through central mechanisms, it may have peripheral local

TABLE 81.3 Properties of Neuraxial Opioids

Property	Lipophilic Opioids	Hydrophilic Opioids
Common drugs	Fentanyl, sufentanil	Morphine, hydromorphone
Onset of analgesia	Rapid onset (5-10 min)	Delayed onset (30-60 min)
Duration of analgesia*	Shorter duration (2-4 h)	Longer duration (6-24 h)
CSF spread	Minimal CSF spread	Extensive CSF spread
Site of action	Spinal ± systemic	Primarily spinal ± supraspinal
Side effects		
Nausea and vomiting	Lower incidence with lipophilic than with hydrophilic opioids	
Pruritus	Lower incidence with lipophilic than with hydrophilic opioids	
Respiratory depression	Primarily early; minimal delay	Both early (<6 h) and delayed (>6 h) possible

*The duration of analgesia varies. *CSF*, Cerebrospinal fluid.

anesthetic properties and has been used as an adjunct for brachial plexus block.[87] Tramadol is effective in treating mild to moderate postoperative pain[88] and is comparable in analgesic efficacy to aspirin (650 mg), with codeine (60 mg), or ibuprofen (400 mg) (see Table 81.2 and Fig. 81.1).[88] The addition of acetaminophen to tramadol (vs. tramadol alone) may decrease the incidence of side effects of tramadol without reducing its analgesic efficacy.[89] Use of tramadol in IV PCA results in similar pain scores when compared with that from IV PCA opioids; however, the side effect profile is different between the two groups (i.e., a more frequent incidence of postoperative nausea/vomiting but lower pruritus with tramadol).[90] Advantages of tramadol for postoperative analgesia include a relative lack of respiratory depression, major organ toxicity, depression of gastrointestinal motility, and a theoretically lower potential for abuse.[86] Common side effects (overall incidence of 1.6%-6.1%) include dizziness, drowsiness, sweating, nausea, vomiting, dry mouth, and headache.[88] Tramadol should be used with caution in patients with seizures or increased intracranial pressure and is contraindicated in those taking monoamine oxidase inhibitors.[88]

Regional Analgesic Techniques

A variety of neuraxial (primarily epidural) and peripheral regional analgesic techniques may be used for the effective treatment of postoperative pain. In general, the analgesia provided by epidural and peripheral techniques (particularly when local anesthetics are used) is site-specific and superior to that with systemic opioids, and use of these techniques may even reduce morbidity and mortality.[13] However, as with all approaches, the risks and benefits should be compared, especially regarding the controversies about use of these techniques in the presence of various anticoagulants.

Single-Dose Neuraxial Opioids

Administration of a single dose of opioid may be efficacious as a sole or adjuvant analgesic drug when administered intrathecally or epidurally. One of the most important factors in determining the clinical pharmacology for a specific opioid is its degree of lipophilicity (vs. hydrophilicity) (Table 81.3). Once they have reached the cerebrospinal fluid (CSF) through direct intrathecal injection or gradual migration from the epidural space, hydrophilic opioids (i.e., morphine and hydromorphone) tend to remain within the CSF and produce a delayed but longer duration of analgesia, along with a generally more frequent incidence of side effects because of the cephalic or supraspinal spread of these compounds. Neuraxial administration of lipophilic opioids, such as fentanyl and sufentanil, provides a rapid onset of analgesia, and their rapid clearance from CSF may limit cephalic spread and the development of certain side effects such as delayed respiratory depression. The site of analgesic action for hydrophilic opioids is overwhelmingly spinal, but the primary site of action (spinal vs. systemic) for single-dose neuraxial lipophilic opioids is not as certain.

The differences in pharmacokinetics between lipophilic and hydrophilic opioids may influence the choice of opioid aiming to optimize analgesia and minimize side effects for a particular clinical situation. Single-dose intrathecal administration of a lipophilic opioid may be useful in situations (e.g., ambulatory surgical patients) in which rapid analgesic onset (minutes) is combined with a moderate duration of action (<4 hours). Single-dose hydrophilic opioid administration provides effective postoperative analgesia and may be useful in patients monitored on an inpatient basis, for whom a longer duration of analgesia would be beneficial.

Single-dose epidural administration of lipophilic and hydrophilic opioids is used to provide postoperative analgesia, with considerations generally similar to those discussed for single-dose intrathecal administration of opioids. A single bolus of epidural fentanyl may be administered to provide rapid postoperative analgesia; however, diluting the epidural dose of fentanyl (typically 50-100 μg) in at least 10 mL of preservative-free normal saline will decrease the onset and prolong the duration of analgesia, possibly as a result of an increase in initial spread and diffusion of the lipophilic opioid. Single-dose epidural morphine is effective for postoperative analgesia and use of a single-dose hydrophilic opioid may be especially helpful in providing postoperative epidural analgesia when the epidural catheter's location is not congruent with the surgical incision (e.g., lumbar epidural catheter for thoracic surgery). Smaller doses of epidural morphine may be required for elderly patients and thoracic catheter sites. Commonly used dosages for intrathecal and epidural administration of neuraxial opioids are provided in Table 81.4.

TABLE 81.4 Dosing of Neuraxial Opioids

Drug	Intrathecal or Subarachnoid Single Dose	Epidural Single Dose	Epidural Continuous Infusion
Fentanyl	5-25 µg	50-100 µg	25-100 µg/h
Sufentanil	2-10 µg	10-50 µg	10-20 µg/h
Alfentanil	—	0.5-1 mg	0.2 mg/h
Morphine	0.1-0.3 mg	1-5 mg	0.1-1 mg/h
Hydromorphone	—	0.5-1 mg	0.1-0.2 mg/h
Extended-release morphine*	Not recommended	5-15 mg	Not recommended

*See package insert for details on dosage and administration.

Doses are based on the use of a neuraxial opioid alone. No continuous intrathecal or subarachnoid infusions are provided. Lower doses may be effective when administered to the elderly or when injected in the cervical or thoracic region. Units vary across agents for single dose (mg vs. µg) and continuous infusion (mg/h vs. µg/h).

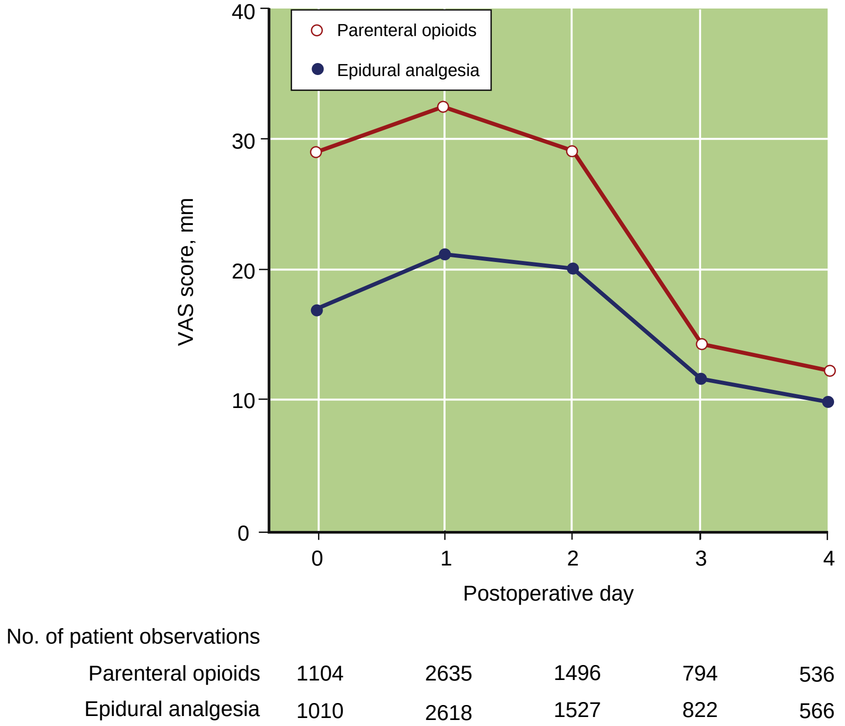

Fig. 81.2 Mean and standard deviation of visual analog pain scores (*y* axis) for both epidural analgesia (represented by *dark blue circles*) and parenteral opioids (represented by *open red circles*) for each postoperative day (*x* axis) up to the fourth day after surgery. (From Block BM, Liu SS, Rowlingson AJ, et al. Efficacy of postoperative epidural analgesia: a meta-analysis. *JAMA.* 2003;290:2455–2463, with permission.)

Continuous Epidural Analgesia

Analgesia delivered through an indwelling epidural catheter is a safe and effective method for management of acute postoperative pain. Postoperative epidural analgesia can provide analgesia superior to that of systemic opioids (Fig. 81.2).[91,92] Of note, however, epidural analgesia is not a generic term but incorporates a wide range of options, including the choice and dose of analgesic drugs, location of catheter placement, and onset and duration of perioperative use.[93] Although this section focuses on the postoperative management of epidural analgesia, intraoperative use of the epidural catheter as part of a combined epidural-general anesthetic technique results in less pain and faster patient recovery immediately after surgery than general anesthesia followed by systemic opioids does. Each of these options may affect the quality of postoperative analgesia, patient-reported outcomes, and even rates of morbidity and mortality.

Analgesic Drugs

Local Anesthetics. Epidural infusion of local anesthetic alone may be used for postoperative analgesia, but in general it is not as effective in controlling pain as local anesthetic-opioid epidural analgesic combinations are.[91,92] The precise location of action of local anesthetics in the epidural space is not clear, and potential sites include the spinal nerve roots, dorsal root ganglion, or spinal cord itself.[94] Epidural infusion of local anesthetic alone may be warranted for postoperative analgesia in an attempt to avoid opioid-related side effects; however, the sole use of local anesthetics is less

TABLE 81.5 Recommended Catheter Insertion Sites for Surgical Procedures

Location of Incision	Examples of Surgical Procedures	Congruent Epidural Catheter Placement
Thoracic	Lung reduction, radical mastectomy, thoracotomy, thymectomy	T4-8
Upper abdominal	Cholecystectomy, esophagectomy, gastrectomy, hepatic resection, Whipple procedure	T6-8
Middle abdominal	Cystoprostatectomy, nephrectomy	T7-10
Lower abdominal	Abdominal aortic aneurysm repair, colectomy, radical prostatectomy, total abdominal hysterectomy	T8-11
Lower extremity	Femoral-popliteal bypass, total hip or total knee replacement	L1-4

L, Lumbar level; *T*, thoracic level.

common than the use of a local anesthetic-opioid combination because of a significant failure rate (from regression of sensory blockade and inadequate analgesia) and relatively high incidence of motor block and hypotension.[93]

Opioids for Epidural Infusion. Opioids may be used alone for postoperative epidural infusion and do not generally cause motor block or hypotension from sympathetic blockade.[93] There are differences between continuous epidural infusion (CEI) of lipophilic (e.g., fentanyl, sufentanil) and hydrophilic (e.g., morphine, hydromorphone) opioids. The analgesic site of action (spinal vs. systemic) of CEI of lipophilic opioids is not clear. Although some data suggest a benefit from epidural (vs. IV) infusion of lipophilic opioids,[95] the overall advantage of administering CEI of lipophilic opioids alone is marginal.[93]

The analgesic site of action for continuous hydrophilic opioid infusion is primarily spinal. Continuous infusion of a hydrophilic opioid may be especially useful for providing postoperative analgesia when the site of catheter insertion is not congruent with the site of surgery or when side effects (e.g., hypotension, motor block) are attributed to the epidural local anesthetic. Use of a continuous infusion rather than intermittent boluses of epidural morphine may result in superior analgesia with fewer side effects. CEI of hydrophilic opioids may provide analgesia superior to that of traditional PRN administration of systemic opioids.

Local Anesthetic-Opioid Combinations. Use of a local anesthetic and an opioid in an epidural infusion may have advantages over infusions consisting of a local anesthetic or opioid alone. When compared with a local anesthetic or opioid alone, a local anesthetic-opioid combination provides superior postoperative analgesia (including improved dynamic pain relief), limits regression of sensory blockade, and possibly decreases the dose of local anesthetic administered, although the effect on the incidence is uncertain.[93] CEI of a local anesthetic-opioid combination also provides analgesia superior to that of IV PCA with opioids.[91] It is unclear whether the analgesic effect of the local anesthetic and opioid in epidural analgesia is additive or synergistic. The choice of local anesthetic for CEI varies. In general, bupivacaine or ropivacaine is chosen because of the differential and preferential clinical sensory blockade with minimal impairment of motor function. Concentrations used for postoperative epidural analgesia are lower than those used for intraoperative anesthesia. The choice of opioid also varies, although many clinicians prefer a lipophilic opioid (e.g., fentanyl, sufentanil) to allow rapid titration of analgesia.[93] Use of a hydrophilic opioid (morphine, hydromorphone) as part of a local anesthetic-opioid epidural analgesic regimen may also provide effective postoperative analgesia. The optimal local anesthetic and opioid dose that provides the lowest pain scores with the fewest medication-related side effects is unknown and further investigation is needed to determine the optimal combinations for other types of surgical procedures with different epidural catheter insertion sites and to compare the efficacy of these optimal continuous infusions with patient-controlled epidural analgesia (PCEA).

Adjuvant Drugs. A variety of adjuvants may be added to epidural infusions to enhance analgesia while minimizing side effects, but none has gained widespread acceptance. Two of the more studied adjuvants are clonidine and epinephrine. Clonidine mediates its analgesic effects primarily through the spinal dorsal horn α_2-receptors on primary afferents and interneurons, as well as the descending noradrenergic pathway, and the epidural dose typically used ranges from 5 to 20 μg/h. Clinical application of clonidine is limited by its side effects: hypotension, bradycardia, and sedation. Hypotension and bradycardia are both dose dependent. Epidural administration of NMDA antagonists, such as ketamine, can theoretically be useful in attenuating central sensitization and potentiating the analgesic effect of epidural opioids, but additional safety and analgesic data are needed.

Location of Catheter Insertion

Insertion of the epidural catheter congruent to the incisional dermatome (i.e., catheter-incision–congruent analgesia) (Table 81.5) results in optimal postoperative epidural analgesia by infusing analgesics to the appropriate incisional dermatomes, providing superior analgesia, minimizing side effects (e.g., lower extremity motor block and urinary retention), and decreasing morbidity.[13,93] When compared with catheter-incision–congruent epidural analgesia, catheter-incision–incongruent epidural analgesia (e.g., low lumbar catheter placement for thoracic procedures) results in increased pain and early removal of the epidural catheter because of ineffective analgesia. By targeting delivery of analgesic drugs to the appropriate dermatomes, catheter-incision–congruent epidural analgesia may result in smaller drug requirements and decreased medication-related side effects. There is a more frequent incidence of lower extremity motor block with the use of lumbar epidural catheters, and an earlier-than-anticipated termination of epidural analgesia may also result. Use of a high thoracic epidural for abdominal or thoracic surgery does not inhibit sympathetic nerve activity in the lower extremities and may result in a relatively infrequent incidence of urinary retention, thus diminishing the need for routine bladder catheterization. Placement of thoracic epidural catheters is relatively safe, and a more frequent incidence of neurologic complications is not documented with placement of a thoracic (vs. lumbar) epidural catheter. Furthermore, the benefits of epidural analgesia in decreasing morbidity in patients undergoing abdominal and thoracic surgery are seen only with thoracic (congruent), not lumbar (incongruent) epidural catheter placement.

Side Effects of Neuraxial Analgesic Drugs

Many medication-related (opioid and local anesthetic) side effects can occur with the use of postoperative epidural analgesia, but before automatically ascribing the cause to the epidural analgesic regimen, other causes should be considered, such as small intravascular volume, bleeding, and low cardiac output leading to hypotension and cerebrovascular accident, pulmonary edema, and evolving sepsis leading to respiratory depression. Standing orders and nursing protocols for analgesic regimens, neurologic monitoring, treatment of side effects, and physician notification about critical variables should be standard for all patients receiving neuraxial and other types of postoperative analgesia (see Box 81.1).

Hypotension. The local anesthetics used in an epidural analgesic regimen may block sympathetic fibers and contribute to postoperative hypotension. Although the precise incidence of postoperative hypotension with postoperative epidural analgesia is uncertain, a systematic review of studies investigating postoperative analgesia found a mean (95% CI) incidence of hypotension for epidural analgesia as 5.6 (3.0%-10.2%).[35] Strategies to treat noncritical hypotension caused by epidural analgesia include decreasing the overall dose of local anesthetic administered (by decreasing the rate or concentration), infusing an opioid epidural alone because it is unlikely that neuraxial opioid administration would contribute to postoperative hypotension, and treating the underlying cause of the decrease in blood pressure.[93]

Motor Block. Use of local anesthetics for postoperative epidural analgesia may also contribute to lower extremity motor block in approximately 2% to 3% of patients, and this may lead to the development of pressure sores in the heels.[96] A metaanalysis noted a mean incidence of motor block of 3.2% with PCEA.[91] A lower concentration of local anesthetic and catheter-incision–congruent placement of epidural catheters for abdominal or thoracic procedures may decrease the incidence of motor block. Although motor block resolves in most cases after stopping the epidural infusion for approximately 2 hours, persistent or increasing motor block should be evaluated promptly, and spinal hematoma, spinal abscess, and intrathecal catheter migration should be considered as part of the differential diagnosis.

Nausea and Vomiting. Nausea and vomiting associated with neuraxial administration of single-dose opioid occurs in up to 50% of patients, and the cumulative incidence in those receiving continuous infusions of opioid may be as high as 80%. The overall data (neuraxial opioids and/or local anesthetic combined) suggest that the incidence of postoperative vomiting is similar between epidural analgesia and systemic opioids, although female patients will exhibit a more frequent incidence regardless of analgesic modality.[97] The incidence of neuraxial opioid-related nausea and vomiting may be dose dependent, although a recent metaanalysis suggested that a larger dose (≥0.3 mg) of intrathecal morphine did not increase the risk of postoperative nausea or vomiting compared to smaller dose (<0.3 mg) of intrathecal morphine.[98] Nausea and vomiting from neuraxial opioids may be related to the cephalad migration of opioid within the CSF to the area postrema in the medulla. Use of fentanyl alone or in combination with a local anesthetic in an epidural infusion is associated with a less frequent incidence of nausea and vomiting than infusions of morphine are. A variety of drugs have been used successfully to treat neuraxial opioid-induced nausea and vomiting, including naloxone, droperidol, metoclopramide, dexamethasone, ondansetron, and transdermal scopolamine.

Pruritus. Pruritus is one of the most common side effects of epidural or intrathecal administration of opioids, with an incidence of approximately 60% versus about 15% to 18% for epidural local anesthetic administration or systemic opioids.[99] A systematic review of studies investigating postoperative analgesia found a mean (95% CI) incidence of pruritus for epidural analgesia as 16.1 (12.8%-20%) versus 13.8 (10.7%-17.5%) for IV opioid PCA.[97] Although the cause of neuraxial opioid-induced pruritus is uncertain, peripheral histamine release is not the cause but may be related to central activation of an “itch center” in the medulla or activation of opioid receptors in the trigeminal nucleus or nerve roots with cephalad migration of the opioid. It is unclear whether the incidence of neuraxial opioid-related pruritus is dose dependent. Many drugs have been evaluated for the prevention and treatment of opioid-induced pruritus, which can be difficult to manage and quite bothersome for some patients. IV naloxone, naltrexone, nalbuphine, and droperidol appear to be efficacious for the pharmacologic control of opioid-induced pruritus. Serotonin receptor antagonists may also be an effective modality in the prevention of neuraxial opioid-induced pruritus. The use of epidural morphine is associated with postpartum reactivation of herpes simplex labialis.

Respiratory Depression. Neuraxial opioids used in appropriate doses are not associated with a more frequent incidence of respiratory depression than that seen with systemic administration of opioids. The incidence of respiratory depression with neuraxial administration of opioids is dose dependent and typically ranges from 0.1% to 0.9%. The incidence of respiratory depression, as defined by a slow

TABLE 81.6 Patient-controlled Epidural Analgesia Regimens

Analgesic Solution*	Continuous Rate (mL/h)	Demand Dose (mL)	Lockout Interval (min)
GENERAL REGIMENS			
0.05% bupivacaine + 4 μg/mL fentanyl	4	2	10-20
0.0625% bupivacaine + 5 μg/mL fentanyl†	4-6	3-4	10-20
0.1% bupivacaine + 5 μg/mL fentanyl	6	2	10-20
0.2% ropivacaine + 5 μg/mL fentanyl	5	2	20
THORACIC SURGERY			
0.0625%-0.125% bupivacaine + 5 μg/mL fentanyl†	3-4	2-3	10-20
ABDOMINAL SURGERY			
0.0625% bupivacaine + 5 μg/mL fentanyl†	4-6	3-4	10-20
0.125% bupivacaine + 0.5 μg/mL sufentanil	3-5	2-3	10-20
0.1%-0.2% ropivacaine + 2 μg/mL fentanyl	3-5	2-5	10-20
LOWER EXTREMITY SURGERY			
0.0625%-0.125% bupivacaine + 5 μg/mL fentanyl†	4-6	3-4	10-20

*Regimens listed are samples of local anesthetic-lipophilic opioid combinations from the literature.
†Patient-controlled epidural analgesic regimens commonly used at the Johns Hopkins Hospital.

respiratory rate, should be less than 1%.[35] The precise incidence of respiratory depression in actual clinical practice may be difficult to determine, as there are many criteria (e.g., respiratory rate, oxygen saturation, partial pressure of carbon dioxide, and need to administer respiratory stimulants/reversal drugs) that have been used to define respiratory depression.[35] Neuraxial lipophilic opioids cause less delayed respiratory depression than hydrophilic opioids, although administration of lipophilic opioids may cause early significant respiratory depression. Delayed respiratory depression is primarily associated with the cephalad spread of hydrophilic opioids, which typically occurs within 12 hours after injection of morphine. Risk factors for respiratory depression with neuraxial opioids include increasing dose, increasing age, concomitant use of systemic opioids or sedatives, possibility of prolonged or extensive surgery, and the presence of comorbid conditions (e.g., OSA). Clinical assessments, such as the respiratory rate, may not reliably predict a patient's ventilatory status or impending respiratory depression. Treatment with naloxone (and airway management if necessary) is effective in 0.1- to 0.4-mg increments; however, because its clinical duration of action is relatively short in comparison to the respiratory depressant effect of neuraxial opioids, continuous infusion of naloxone (0.5-5 μg/kg/h) may be needed.[100] Practice guidelines for the prevention, detection, and management of respiratory depression associated with neuraxial opioid administration have been published.[101]

Urinary Retention. Urinary retention associated with the neuraxial administration of opioids is the result of an interaction with opioid receptors in the spinal cord that decreases the detrusor muscle's strength of contraction. The incidence of urinary retention is more frequent with neuraxially administered opioids than when given systemically. Urinary retention does not depend on the opioid dose and may be treated with the use of low-dose naloxone, although at the risk of reversing the analgesic effect. Urinary retention occurred in 23.0% of patients, with the most frequent rate in those receiving epidural analgesia.[97] However, the exact incidence of urinary retention seen clinically may be difficult to determine because patients who undergo major surgical procedures are often routinely catheterized.

Patient-Controlled Epidural Analgesia

Epidural analgesia has traditionally been delivered at a fixed rate or as a CEI; however, the administration of epidural analgesia through a patient-controlled device (PCEA) has become more common. Like IV PCA, PCEA allows individualization of postoperative analgesic requirements and may have several advantages over CEI, including lower drug use and better patient satisfaction. PCEA may also provide analgesia superior to that afforded by IV PCA.[91]

PCEA is a relatively safe and effective technique for postoperative analgesia on routine surgical wards. Observational data from two series of over 1000 patients each reveal that more than 90% of patients with PCEA receive adequate analgesia, with a median pain score of 1 (of a possible 10) at rest and 4 with activity.[102,103] The incidence of side effects is 1.8% to 16.7% for pruritus, 3.8% to 14.8% for nausea, 13.2% for sedation, 4.3% to 6.8% for hypotension, 0.1% to 2% for motor block, and 0.2% to 0.3% for respiratory depression.[102,103] These rates are favorable and comparable to those reported with CEI.

The optimal PCEA analgesic solution and delivery parameters are unclear. Use of a continuous or background infusion in addition to the demand dose is more common with PCEA than with IV PCA and may provide analgesia superior to that of the use of a demand dose alone.[104] In general, most acute pain specialists have gravitated toward a variety of low-concentration local anesthetic-opioid combinations (Table 81.6) in an attempt to improve analgesia while minimizing side effects, such as motor block and respiratory depression. As for CEI, addition of an opioid to the local anesthetic can provide analgesia superior to that of either analgesic alone. A lipophilic opioid is usually chosen because its rapid analgesic effect and shorter duration of action may be more suitable for use with PCEA.[102] Use of lower concentrations of a local anesthetic (e.g., bupivacaine, ropivacaine) may provide excellent analgesia without significant motor block.[105]

Benefits of Epidural Analgesia

Use of perioperative epidural anesthesia and analgesia, especially with a local anesthetic-based analgesic solution, can attenuate the pathophysiologic response to surgery and may be associated with a reduction in mortality and morbidity when compared with analgesia with systemically administered opioids.[13,14] Metaanalysis of randomized data (141 trials enrolling 9559 subjects) found that perioperative use of neuraxial anesthesia and analgesia (vs. general anesthesia and systemic opioids) reduced overall mortality (primarily in orthopedic patients) by approximately 30%.[106] Use of epidural analgesia can decrease the incidence of postoperative gastrointestinal, pulmonary, and possibly cardiac complications.[13,107]

By inhibiting sympathetic outflow, decreasing the total opioid dose, and attenuating spinal reflex inhibition of the gastrointestinal tract, postoperative thoracic epidural analgesia can facilitate return of gastrointestinal motility without contributing to anastomotic bowel dehiscence.[107,108] Randomized clinical trials demonstrate that use of postoperative thoracic epidural analgesia with a local anesthetic-based analgesic solution allows earlier return of gastrointestinal function and fulfillment of discharge criteria.[109] When compared with those who receive epidural opioids for postoperative analgesia, patients who receive epidural local anesthetics have an earlier return of gastrointestinal motility after abdominal surgery.[109]

Perioperative use of epidural analgesia with a local anesthetic-based regimen in patients undergoing abdominal and thoracic surgery decreases postoperative pulmonary complications,[110,111] presumably by preserving postoperative pulmonary function through providing superior analgesia and thus reducing "splinting" behavior and attenuating the spinal reflex inhibition of diaphragmatic function.[112] A metaanalysis of 48 randomized clinical trials[113] and another large, randomized clinical trial[114] demonstrated that use of thoracic epidural analgesia with a local anesthetic-based regimen decreased the incidence of pulmonary infections and complications. However, patients who received postoperative epidural opioids, intercostal blocks, wound infiltration, or intrapleural analgesia did not have a significant decrease in the incidence of pulmonary complications.[113] A subsequent meta-analysis confirmed the benefits of thoracic epidural analgesia in decreasing perioperative pulmonary complications.[115]

Use of postoperative thoracic, but not lumbar, epidural analgesia may decrease the incidence of postoperative myocardial infarction, possibly by attenuating the stress response and hypercoagulability, improving postoperative analgesia, and providing favorable redistribution of coronary blood flow. The finding that only thoracic epidural analgesia decreases the incidence of postoperative myocardial infarction corroborates experimental data on the physiologic benefits of thoracic epidural analgesia, such as a reduction in the severity of myocardial ischemia or size of infarction, attenuation of sympathetically mediated coronary vasoconstriction, and improvement of coronary flow to areas at risk for ischemia. The use of thoracic epidural analgesia in patients undergoing cardiac surgery decreased the risk of postoperative supraventricular arrhythmias and respiratory complications.[116]

Although postoperative epidural analgesia decreases postoperative gastrointestinal, pulmonary, and possibly cardiac morbidity, the benefits of postoperative epidural analgesia are not as evident in other areas, such as postoperative coagulation, cognitive dysfunction,[117] and immune function. While the use of *intra*operative regional anesthesia decreases the incidence of hypercoagulable-related events (e.g., deep venous thrombosis, pulmonary embolism, vascular graft failure),[106] *post*operative epidural analgesia does not obviously decrease the incidence of hypercoagulable-related events.

The benefits of postoperative epidural analgesia are optimized when the epidural catheter is inserted in a location corresponding to the dermatomes covered by the surgical incision (i.e., catheter-incision–congruent analgesia), which results in a smaller dose of drug administered and decreased incidence of drug-induced side effects, such as pruritus, nausea, vomiting, urinary retention, motor block, and hypotension.[102] When compared with catheter-incision–incongruent epidural analgesia, catheter-incision–congruent analgesia provides earlier return of gastrointestinal function, a lower incidence of myocardial infarction, and superior analgesia.[112] The ability of postoperative epidural analgesia to attenuate postoperative pathophysiology and improve outcomes also depends on the type of drugs used (opioids vs. local anesthetics). Maximal attenuation of perioperative pathophysiology occurs with the use of a local anesthetic-based epidural analgesic solution. The use of a local anesthetic-based (vs. opioid-based) analgesic solution is associated with earlier recovery of gastrointestinal motility after abdominal surgery[109] and less frequent occurrence of pulmonary complications.[113] Epidural analgesia is not a generic entity because different catheter locations and analgesic regimens may differentially affect perioperative morbidity.

It is unclear whether perioperative epidural analgesia may improve patient-reported outcomes.[112] Use of postoperative epidural analgesia may be associated with an improvement in postoperative analgesia and patient-reported outcomes such as patient satisfaction[34] and HRQL.[19] When compared with systemic opioids, epidural local anesthetics consistently provide superior analgesia.[91,92] Although the concept of satisfaction is complex and difficult to measure accurately, the analgesic benefits of postoperative epidural analgesia may contribute to greater patient satisfaction[34] and improved HRQL.[19]

There may be a possible link between the perioperative use of regional anesthesia/analgesia and a decrease in cancer recurrence.[118] There are several hypothetical reasons why the perioperative use of regional anesthesia and analgesia would be of benefit in patients undergoing cancer surgery, including attenuation of perioperative immunosuppression and decreased use of inhaled anesthetics/opioids. A regional anesthetic-induced sympathectomy should increase blood flow to the extremities with subsequent improvement in tissue oxygenation and a potential favorable local anesthetic effect on tumor-cell killing. However, there are multiple factors that may potentially affect cancer recurrence and the impact of perioperative regional analgesic techniques on a long-term outcome such as cancer recurrence is uncertain at this time. Use of neuraxial anesthesia/analgesia for total hip or knee replacement may decrease the risk of surgical site infections compared with general anesthesia.[119]

Risks With Epidural Analgesia

The benefits of perioperative epidural anesthesia-analgesia must be weighed against the risks associated with this technique. Some complications are associated with placement of an epidural catheter, and several risks related to the use of indwelling epidural catheters (e.g., epidural hematoma and abscess) should be discussed in the context of postoperative epidural analgesia. A review of neurologic complications after regional anesthesia revealed that the rate of neurologic complications after central neuraxial blockade is less than 4 in 10,000 (0.04%); the rate of neuropathy after a peripheral nerve block is less than 3 in 100 (3%).[120] However, permanent neurologic injury after either central neuraxial or peripheral nerve block is rare in contemporary anesthetic practice.[120] Elements of routine monitoring of patients receiving neuraxial analgesia are presented in Box 81.1.

The concurrent use of anticoagulants and neuraxial anesthesia and analgesia has always been a relatively controversial issue but has been highlighted over the past decade by the increased incidence of spinal hematoma after the introduction of low-molecular-weight heparin in North America in 1993.

Different types and classes of anticoagulants have different pharmacokinetic properties that affect the timing of neuraxial catheter or needle insertion and catheter removal. Despite many observational and retrospective studies investigating the incidence of spinal hematoma in the setting of various anticoagulants and neuraxial techniques, no definitive conclusion regarding the absolute safety of neuraxial anesthesia and anticoagulation has been reached. The American Society of Regional Anesthesia and Pain Medicine (ASRA) lists a series of guidelines based on the available literature for administration (insertion and removal) of neuraxial techniques in the presence of various anticoagulants, including oral anticoagulants (warfarin), antiplatelet agents, fibrinolytics-thrombolytics, standard unfractionated heparin, and low-molecular-weight heparin.[121] The ASRA guidelines include the concept that the timing of neuraxial needle or catheter insertion or removal should reflect the pharmacokinetic properties of the specific anticoagulant. Frequent neurologic monitoring is essential. Concurrent use of multiple anticoagulants may increase the risk of bleeding, and the analgesic regimen should be tailored to facilitate neurologic monitoring, which may be continued in some cases for 24 hours after removal of the epidural catheter. Although the ASRA guidelines were developed with the latest available literature, these guidelines are limited by the relatively rare incidence of epidural hematoma; there are observational studies during which procedures (e.g., epidural catheter removal) are performed outside the boundaries presented in the ASRA guidelines.[122] A version of the ASRA guidelines on neuraxial anesthesia and anticoagulation[121] can be found on their website (www.asra.com), and some of these statements address the newer anticoagulants. Finally, the risk of epidural hematoma may be different for obstetric versus surgical patients.[123]

Infection associated with postoperative epidural analgesia may result from exogenous or endogenous sources.[93] Serious infections (e.g., meningitis, spinal abscess) associated with epidural analgesics are rare (<1 in 10,000),[124] although a more frequent incidence has been observed (approximately 1 in 1000-2000).[124] Closer examination of the studies that reported a more frequent incidence of epidural abscess reveals that the patients had a relatively longer duration of epidural analgesia or coexisting immunocompromising or complicating diseases (e.g., malignancy, trauma).[93] Use of epidural analgesia in the general surgical population with a typical duration of postoperative catheterization (approximately 2-4 days) is not generally associated with epidural abscess formation.[102] Even though serious infectious complications are rare after short-term (<4 days) epidural infusions, there may be a relatively more frequent incidence of superficial inflammation or cellulitis (4%-14%) and an even higher rate of catheter colonization (20%-35%), with the proportion of positive cultures increasing with longer duration of catheterization; however, the catheter colonization rate may not be a good predictor of infection of the epidural space.[125] A practice advisory from the ASA discussing the prevention, diagnosis, and management of infectious complications associated with neuraxial techniques has been published.[126]

Although epidural analgesia may provide superior postoperative analgesia, migration of the epidural catheter out of the epidural space and into the intrathecal, intravascular, or subcutaneous space decreases the effectiveness of this technique. The failure rate (i.e., earlier-than-anticipated discontinuation of the catheter for any reason, placement of a nonfunctioning epidural catheter) ranges from approximately 6% to 25%, with many centers reporting a rate between 10% and 20%, but the incidence of actual premature epidural catheter dislodgement may be less frequent (mean, 5.7%; 95% confidence interval, 4.0%-7.4%).[127,102] Fortunately, the rate of intrathecal and intravascular migration of an epidural catheter is most likely much less frequent than the failure rate. Some authors have gone further to define a successful epidural as the one that provides good pain relief and facilitates postoperative mobilization and rehabilitation for as long as the catheter is in place.[128] In that sense, determining failure rate maybe even more difficult and only local institutional audits are able to define local failure rate.

Despite the less frequent occurrence of intravascular and intrathecal migration of postoperative epidural catheters, use of an epinephrine-containing test dose, administration of local anesthetic in fractionated doses, and aspiration of the catheter before bolus administration of local anesthetics may prevent complications (e.g., high or total spinal, seizures, neurotoxicity).[93] The issue of whether lower extremity compartment syndrome can be consistently masked by the use of a local anesthetic-based epidural analgesic regimen is unresolved because use of systemic opioid analgesia has also been associated with a delayed diagnosis of compartment syndrome.[129]

Peripheral Regional Analgesia

The use of peripheral regional analgesic techniques as a single injection or continuous infusion can provide site-specific analgesia superior to that with systemic opioids[130] and may even result in improvement in various outcomes.[131] A variety of wound infiltration and peripheral regional techniques (e.g., brachial plexus, lumbar plexus, femoral, sciatic-popliteal, and scalp nerve blocks) can be used to enhance postoperative analgesia. Peripheral regional techniques may have several advantages over systemic opioids (i.e., superior analgesia and decreased opioid-related side effects) and neuraxial techniques (i.e., decreased risk for spinal hematoma and less hemodynamic instability).[132]

A one-time injection of local anesthetic for peripheral regional techniques may be used primarily for intraoperative anesthesia or as an adjunct to postoperative analgesia. When compared with placebo, peripheral nerve blocks with local anesthetics provide superior analgesia and are associated with reduced opioid use, decreased opioid-related side effects, and improvement in patient satisfaction.[132] The duration of postoperative analgesia resulting from the local anesthetic in the peripheral nerve block varies but may last up to 24 hours after injection. Additives to local anesthetics can also increase the duration of action of local anesthetic and improve the quality of nerve blocks. Some of these adjuvants include dexamethasone, clonidine, and dexmedetomidine.[133] An earlier systematic review indicated that local anesthetics may also provide effective wound infiltration analgesia postoperatively for a variety of procedures.[134] A more recent meta-analysis suggested that local anesthetic administered via wound catheters may not reduce pain intensity after surgery.[135]

Continuous infusions of local anesthetics can be administered through peripheral nerve catheters. There are many methods to insert peripheral nerve catheters, including nerve stimulation and ultrasound guidance.[136] RCTs suggest that use of peripheral regional analgesia may facilitate postoperative rehabilitation as evidenced by accelerated resumption of passive joint range-of-motion, decrease in time until discharge readiness, and earlier actual discharge from the hospital or rehabilitation center.[136,137] Continuous peripheral nerve blocks may be used in the outpatient (home) setting typically using a portable ambulatory pump.[136] When compared with systemic opioids, use of continuous infusions or patient-controlled peripheral analgesia results in superior analgesia, decreased opioid-related side effects, and greater patient satisfaction.[130,132] The optimal parameters (i.e., local anesthetic, concentration, opioid, adjuvants, and continuous vs. PCA vs. intermittent boluses) for peripheral analgesia are still being determined. With the evolution of the ultrasound guidance technology and description of new block technique, peripheral nerve blocks are now more integrated into new clinical pathways.

Truncal Blocks

Several nonepidural/truncal regional analgesic techniques can be used for the management of postoperative thoracic and abdominal pain. Some of these techniques are well established and others are relatively new, including; paravertebral and intercostal blocks, transversus abdominis plane (TAP) blocks, quadratus lumborum blocks,[138] erector spinae plane blocks,[139] interpleural (intrapleural) analgesia, and cryoanalgesia. Thoracic paravertebral block has been used for thoracic, breast, and upper abdominal surgery and for the treatment of rib fracture pain.[140] Possible sites of analgesia for a thoracic paravertebral block include direct somatic nerve, sympathetic nerve, and epidural blockade.[140] A thoracic paravertebral block can be administered as a single injection or as continuous infusion through a catheter, may provide analgesia equal or superior to that of thoracic epidural analgesia, and is a valuable alternative to thoracic epidural analgesia.[128,141] Paravertebral blocks may be especially useful in providing postoperative analgesia after breast surgery.[142] When compared to thoracic epidural analgesia, paravertebral analgesia has been shown to provide equivalent analgesia but with a better side effect profile (e.g., lower incidence of hypotension) and also lower the risk of postoperative pulmonary complications.[141,143] Continuous infusions of local anesthetics through a paravertebral catheter are preferable to intermittent boluses, as the former is associated with lower pain scores.[144]

TAP nerve block is an approach for blocking the abdominal wall neural afferents to provide postoperative analgesia. Typically performed under ultrasound guidance, TAP blocks have been mostly described in adult patients (with some in pediatric patients) and used in a variety of surgical patients.[145,146] Several systematic reviews indicate that TAP blocks may reduce postoperative morphine requirements, nausea and vomiting, and possibly the severity of pain after abdominal surgery.[145,147] Although superior early postoperative analgesia appears to occur (within 24 hours of surgery), the surgical procedures, analgesic dosing, techniques, and timing for optimal analgesia following TAP block need further examination. A host of truncal blocks have been described to provide analgesia for the thoracic and abdominal wall. These blocks are yet to be compared head-to-head with well-established analgesic modality.

The analgesic efficacy and the mechanism of interpleural analgesia are no longer controversial (i.e., sensory or sympathetic block, or both). Interpleural analgesia is inferior to epidural and paravertebral analgesia for control of postoperative pain, preservation of lung function after thoracotomy, and reduction of postoperative pulmonary complications.[113] Intercostal blocks may provide short-term postoperative analgesia and may be repeated postoperatively; however, the incidence of pneumothorax increases with each intercostal nerve blocked (1.4% per nerve, with an overall incidence of 8.7% per patient).[148] Like interpleural analgesia, intercostal blocks do not reduce the incidence of pulmonary complications postoperatively when compared with epidural analgesia.[113]

Intraarticular and Local Infiltration Analgesia

Local peripheral administration of opioids (e.g., intraarticular injection after knee surgery) may theoretically provide analgesia for up to 24 hours after surgery and decrease the incidence of chronic pain, as peripheral opioid receptors are found on the peripheral terminals of primary afferent nerves and are upregulated during inflammation of peripheral tissues. Results of the several randomized clinical trials investigating this topic have been summarized. A subsequent qualitative systematic review found no evidence for analgesic effect of intraarticular morphine after knee arthroscopy.[149] A systemic effect of intraarticularly injected morphine cannot be excluded. A systematic review suggested that intraarticular administration of NSAIDs may provide clinically relevant peripheral analgesia.[150] Intraarticular injection of local anesthetics may provide a limited duration of postoperative analgesia, but the clinical benefit from intraarticular injection of local anesthetics is unclear. High-volume infiltration of local anesthetic (LIA) is especially popular after total knee arthroplasty (TKA). Proponents cite its simplicity and no requirement for postoperative management as reasons to adopt the technique. A systematic review of 27 RCTs on LIA for TKA and total hip arthroplasty (THA) showed that LIA for TKA was associated with reduced pain scores and opioid requirements up to 72 hours after surgery.[151,152] Clinicians should be aware that there have been cases of glenohumeral chondrolysis reported in association with postarthroscopy infusion of local anesthetic.[153]

OTHER TECHNIQUES

Other nonpharmacologic techniques, such as transcutaneous electrical nerve stimulation (TENS), acupuncture, exercise/activity, and psychological approaches, can be used to alleviate postoperative pain. The mechanism by which TENS produces analgesia is unclear but may be related to modulation of nociceptive impulses in the spinal cord, release of endogenous enkephalins, or a combination of these, and other, mechanisms. Although the analgesic efficacy of these techniques is controversial, TENS and acupuncture may provide postoperative analgesia, decrease postoperative opioid requirements, reduce opioid-related side effects, and attenuate activation of the sympathoadrenal system. In general, all these approaches to postoperative pain are relatively safe, noninvasive, and devoid of the systemic side effects seen with other analgesic treatment options.[154] TENS may be of benefit in providing postoperative analgesia and decreasing analgesic consumption.[155,156] Early mobilization and activity therapy improve functional outcomes following orthopedic surgical procedures[157] and are effective in reducing pain behaviors in animal models of surgical neuropathic pain.[158] Although some methodologic issues have been raised with many of the available trials and the precise role of these treatments in postoperative pain management is not clear, they represent alternative therapies to add to the clinician's armamentarium. In the case of exercise and activity programs, these represent inexpensive and easily available therapies.

While this chapter has focused on the neurobiology of nociception and pharmacologic treatments available for the treatment of postoperative pain, the experience of pain is complex, multifaceted, and "an unpleasant sensory and emotional experience," as defined in part by the International Association for the Study of Pain. The differential behavior response to surgical incision may be related to global (i.e., personality, gender, age, and culture) and specific (i.e., fear, depression, anger, and coping) psychological factors.[159] Cognitive therapy and behavior therapy may be efficacious in reducing pain and alleviating psychological factors associated with pain.[160] Identifying and addressing psychological factors can reduce pain, improve the efficacy of pharmacologic analgesics, and diminish patients' distress, in part through enhancement of the placebo effect.[159] Although the placebo effect may have a psychological origin, the placebo response may exert part of its effects through activation of endogenous opioids and be useful in reducing the intensity of pain.[161]

POSTOPERATIVE ANALGESIA IN SPECIAL POPULATIONS

The foregoing discussion has provided a general approach to the principles and practice of acute postoperative pain management, but this approach may need to be modified for certain populations that have unique anatomic, physiologic, pharmacologic, affective, and cognitive issues. Management of acute pain should be tailored to the specific needs of a particular population. Although each topic by itself could merit a separate chapter in some textbooks, the general principles and essence of the issues associated with each population are outlined, and references are made to other more extensive sources.

OPIOID-TOLERANT PATIENTS: PATIENTS WITH PREEXISTING PAIN

Opioid-tolerant patients can be categorized into three groups: (1) those who have chronic pain for which they receive opioid-based analgesic therapy, (2) those who use opioids recreationally as a result of a substance use disorder, and (3) those who take opioids for a combination of numbers (1) and (2). Regardless of the reason the individual is using opioids, the management of their perioperative pain is considerably more challenging than for those who are opioid-naïve.

Even though there is no specific threshold or timeframe for when a patient becomes opioid tolerant, the FDA has provided guidelines for defining the opioid tolerant patient.[162] In summary, patients considered opioid-tolerant are those who are regularly taking at least: 60 mg oral morphine per day; 25 μg transdermal fentanyl per hour; 30 mg oral oxycodone per day; 8 mg oral hydromorphone per day; 25 mg oral oxymorphone per day; or an equianalgesic dose of another opioid for one week or longer.

Postoperative pain may be difficult to manage in opioid-tolerant patients because the standard approaches used for baseline assessment and assessment of response to therapy in opioid-naïve or research patients are often less accurate for opioid-tolerant patients. Although opioid-tolerant patients require larger doses of analgesic medications (in addition to their baseline pain medication requirements) in the immediate postoperative period, many healthcare providers still do not provide adequate postoperative pain relief, in part because of the fear of addiction or medication-related side effects. In dealing with patients with chronic opioid use, healthcare providers often mistakenly interchange several pharmacologic terms (i.e., tolerance, physical dependence, and addiction), a practice that may contribute to misunderstanding and inappropriate treatment decisions.

Tolerance refers to the pharmacologic property of an opioid in which an increasing amount is needed to maintain a given level of analgesia. *Physical dependence* is another pharmacologic property of opioids characterized by the occurrence of a withdrawal syndrome on abrupt discontinuation of the opioid or administration of an antagonist. Tolerance and physical dependence are pharmacologic properties of opioids and are not synonymous with the aberrant psychological state or behavior associated with *addiction*, a chronic disorder characterized by the compulsive use of a substance resulting in physical, psychological, or social harm to the user, and continued use despite that harm.

Several principles of pain assessment and treatment can be applied to the postoperative management of opioid-tolerant patients. The physician should expect high self-reported pain scores; base treatment decisions on objective pain

TABLE 81.7 Guidelines for Equianalgesic Dosing of Opioid Agonists

	RELATIVE STRENGTH COMPARED	EQUIANALGESIC DOSE (MG)	
Drug	**With Morphine**	**Oral**	**Parenteral**
Morphine	–	30	10
Buprenorphine	Much, much stronger	N/A	0.4 (7.5 µg/h TD)
Butorphanol	Much stronger	N/A	2
Codeine	Weaker	200	125
Fentanyl	Much, much stronger	N/A	0.1 (16.5 µg/h TD)
Hydrocodone	Equivalent to mildly weaker	30	N/A
Hydromorphone	Much stronger	7.5	1.5
Levophanol	Much stronger	4	N/A
Methadone	Stronger	10	5
Nalbuphine	Equivalent	N/A	10
Oxycodone	Stronger	20	N/A
Oxymorphone	Stronger	10	1
Pentazocine	Weaker	150	60
Tapentadol	Weaker	100	N/A
Tramadol	Much weaker	300	N/A

Equianalgesic doses are approximate and intended to serve only as an estimate of opioid requirements. Actual doses may vary, in part because of wide interpatient variability in response to opioids. Doses should be individualized and gradually titrated to effect. *TD*, Transdermal.

assessment (e.g., ability to breathe deeply, cough, ambulate) in conjunction with patients' self-reported pain scores; recognize the need to identify and treat two major problems, maintenance of a basal opioid requirement and control of incisional pain; and recognize that detoxification is not usually an appropriate goal in the perioperative period.[163-165]

The treatment of patients with prior opioid use requires the management of the expectations of the patient, the patient's family, and the physician's surgical colleagues. The goal of inpatient management of pain in patients with chronic pain or acute-on-chronic pain is to stabilize and rationalize (if necessary) the patient's outpatient pain medication regimen. The goal is not to treat long-standing persistent pain that has been managed on an outpatient basis, because it is unlikely in the very limited time in which you are a member of the patient's care team that you will be able to make a substantial positive difference. Therefore, several general strategies can be used for the treatment of postoperative pain in an opioid-tolerant patient or in a patient with chronic pain who is receiving opioids. Although patients with chronic pain are not synonymous with opioid-tolerant patients, many of these patients are also opioid tolerant, and the same general principles and strategies discussed earlier may be applied to these patients as well. The physician can create a treatment plan early and discuss it with the patient, surgical team, and nursing staff; replace the patient's baseline or basal opioid requirements postoperatively; anticipate an increase in postoperative analgesic requirements[166]; maximize the use of adjuvant drugs; consider the use of regional analgesic techniques; and plan for the transition to an oral regimen. The physician, patient, and other providers need to be aware that the nonopioid adjuvant medications (not including tramadol, NSAIDs, acetaminophen) may be started while the patient is an inpatient, but they are unlikely to have substantial impact on the patient's chronic pain while hospitalized. Recognizing and addressing non-nociceptive sources of distress may be especially important for patients with chronic pain.

Administration of a PRN analgesic regimen alone for opioid-tolerant patients is discouraged because replacing the basal opioid requirement in the postoperative period can optimize pain relief and possibly prevent opioid withdrawal. Basal opioid requirements can be administered systemically (typically intravenously) until the patient can tolerate an oral analgesic regimen.[30] For example, 50% to 100% of the patient's baseline opioid requirement can be administered by an IV PCA regimen, with a demand dose to cover the additional incisional pain. Conversion tables (Table 81.7) may facilitate equianalgesic conversion of opioids (i.e., different routes of administration of one opioid or conversion between two different opioids); however, these tables provide only estimations to assist healthcare providers in initiating opioid titration.[167]

Opioid-tolerant patients generally require increased postoperative analgesic levels, including a larger demand dose.[30,166] Patients may need frequent adjustment of the IV PCA demand dose or continuous infusion, depending on the analgesic requirements. There is individual variability in response to different opioids, and if a decision is made to switch opioids, the choice of opioid is probably not as important as using an equianalgesic dose. Patients may experience different side effects with different opioids, and rotating to another opioid may be reasonable if the patient is not tolerating the first opioid.[168] Adjuvant drugs such as NSAIDs should be administered on a regularly scheduled basis to optimize analgesic efficacy and possibly provide an opioid-sparing effect. Use of regional analgesic techniques with neuraxial opioids may provide excellent analgesia in opioid-tolerant patients while theoretically preventing withdrawal symptoms, although the clinician should be prepared to diagnose and treat perioperative opioid withdrawal in these patients.

After the patient is tolerating oral intake, conversion from IV opioids to oral form that would be more suitable for discharge home may be initiated. Opioid-tolerant patients can generally be converted to a combination of a regularly administered, controlled-release formulation of opioid (i.e., sustained-release morphine) and short-acting, immediate-release opioid on a PRN basis. Although conversion of IV opioid to an oral form can be accomplished over a period of 24 hours in opioid-tolerant patients, this process may take longer in extremely difficult cases. In patients with a relatively high basal requirement of IV opioid (e.g., high, continuous background infusion of IV opioid PCA), clinicians should be aware not to abruptly discontinue the IV infusion of opioid during this transition but ideally decrease the high basal requirement of IV opioid in a stepwise fashion to account for the slower onset of the sustained-release. Converting from an IV to an oral form of opioid is not an exact science, and the conversion tables available can serve only as a rough guide because of significant interpatient and intrapatient variability in the sensitivity to opioids, lack of complete cross-tolerance between opioids (which may lead to greater than anticipated potency of a new opioid), and changes in the level of pain, which may rapidly decrease in the immediate postoperative period.[167] Because of these factors, conversion of approximately 50% to 75% of the equianalgesic dose to a sustained-release preparation of opioid or a transdermal fentanyl patch, with the remainder converted to a short-acting opioid delivered on a PRN basis, may be a reasonable starting point in patients whose pain is reasonably controlled, although additional titration may be necessary.

Although opioids are most commonly used in these patients, with consultation of the inpatient pain services (if available), the physicians can consider the use of analgesic (low-dose) ketamine.[169] Ketamine can be given as a basal infusion as a part of the ketamine PCA or a combination ketamine and opioid PCA, subcutaneously or orally. Ketamine may have significant advantages (such as greater analgesic response, less frequent rates of respiratory depression, and minimal impact on the gastrointestinal system) over continued opioid use in the opioid-tolerant or chronic pain patient in the postoperative setting.

Patients taking medications containing buprenorphine have some similar challenges to those of the opioid-tolerant or chronic pain patient in the perioperative setting, but these patients also have the added difficulties associated with the partial *mu* opioid agonist pharmacodynamics of buprenorphine. Although buprenorphine is a partial agonist, when given in conjunction with a full *mu* opioid agonist, it functions as a pharmacologic antagonist. It also possesses variable time to dissociation from the opioid receptor; therefore, when used in combination with a full agonist, it is challenging to time the switch from antagonism of the *mu*-opioid receptor action to the full agonism of morphine, oxycodone, hydromorphone, and other similar opioids. This can create a dangerous situation in which a previously appropriate dosage of one of the full agonists becomes enough to result in respiratory depression or other dose-related adverse events. Although it is ideal to not take buprenorphine 3 days in advance of surgery, it is often not feasible in many of our surgical settings in which patients are first seen by the anesthesiologist directly prior to the operation. Also, a similar situation can occur in patients who are taking buprenorphine as opioid replacement therapy for an opioid use disorder (OUD) (otherwise known as medication-assisted therapy) where discontinuing buprenorphine can precipitate withdrawal symptoms and the substitution of a full opioid agonist may provoke OUD relapse. In situations in which patients have not discontinued their buprenorphine therapy well in advance of their surgery, the patient should receive their baseline buprenorphine via sublingual or transdermal routes. Alternatively, and if necessary, convert the patient buprenorphine requirements to an IV equivalent while the patient is in the immediate perioperative period. Although the patient is maintained on a stable dosage of buprenorphine, additional full agonist opioids may be titrated to pain reduction, or alternatively, nonopioid adjuvants (including clonidine, ketamine, lidocaine, or dexmedetomidine) can be used instead of opioids for the patient's postoperative pain. Some authors suggest stopping buprenorphine preoperatively and switching to a short-acting opioid, or methadone, to prevent withdrawal symptoms if the surgery is major and will generate severe pain. The choice of methadone is a reasonable one, as it is an effective full opioid agonist but also has a long half-life, thereby providing benefit for continuation of medication-assisted treatment (MAT). Regardless of the approach, coordinated communication between the acute pain team, surgical service, and the primary buprenorphine prescriber should take place to make sure that the patient eventually goes back to their prescribed buprenorphine dose.[170] Sometimes, the logistics of this process can be difficult. Therefore, more often than not, anesthesiologists opt to continue buprenorphine perioperatively and optimize all components of multimodal analgesia for postoperative pain management. Regional anesthesia and local infiltration techniques should be used whenever feasible in these patients.[171]

PEDIATRIC PATIENTS

As in adults, undertreatment of acute pain occurs in a substantial percentage of children.[172] Pediatric patients continue to be undertreated.[166] In addition to anatomic, physiologic, pharmacodynamic, and pharmacokinetic differences between children and adults, there are barriers unique to pediatric patients that may interfere with effective postoperative pain control. Control of postoperative pain is important in pediatric patients because poor pain control may result in increased morbidity or mortality.[173]

Some of the most important barriers to pain control in pediatric patients are the myths that children and infants do not feel pain, that pain is not remembered, and that there is no untoward consequence of experiencing pain.[172] These incorrect assumptions about pain in pediatric patients may hinder management of pediatric pain. Because of developmental, cognitive, and emotional differences, assessment of pain in pediatric patients can be difficult. Pediatric patients may have difficulty conceptualizing and quantifying a subjective experience such as pain. The lack of routine assessment and reassessment of pain may interfere with effective acute pain management.[172] Special scales are available to assist young children in self-reporting of pain; however, interpretation of behavior and physiologic parameters may be used to estimate pain intensity in preverbal children or those who cannot self-report their pain. Furthermore, assessing pain in children with intellectual disabilities presents unique challenges.[174]

A plan for postoperative pain management should be discussed with the family and patient before surgery, as pediatric patients may have many anxieties about pain and analgesic use after surgery. In general, the oral route of analgesic administration is preferred for mild to moderate pain. IV or regional analgesia is appropriate for moderate to severe postoperative pain.[172,175] Use of intramuscular injections is strongly discouraged because of the pain associated with injection and variable absorption of analgesic medications. Fear of needles may inhibit control of postoperative pain because pediatric patients may choose to suffer in silence rather than receive a painful and anxiety-provoking intramuscular injection. Addressing medication-related side effects is important to alleviate patient-related distress and improve compliance with the postoperative analgesic regimen.

Use of an IV PCA device allows individualization of analgesic requirements and offers pediatric patients autonomy. Children as young as 4 years have the cognitive and physical capability to appropriately use an IV PCA device.[176] Although morphine is the standard by which other opioids are compared, morphine does not appear to have an analgesic advantage over other opioids (e.g., hydromorphone) when given in equianalgesic doses. Because of toxicity from its metabolite and much better alternatives, meperidine should not be used in the pain management of pediatric (or adult) patients.[172] A metaanalysis examining whether the addition of a background or continuous infusion to an IV PCA opioid regimen would be associated with an increased risk of respiratory depression indicated that the addition of a continuous or background infusion was associated with a higher incidence of respiratory events in adult but not in pediatric patients.[32] Nurse- or parent-controlled analgesia is also effective and may be used in certain circumstances, but close monitoring of the patient may be needed because significant respiratory depression occurs in approximately 1.7% of patients, although some data suggest that children receiving PCA by proxy do not have a higher incidence of adverse events compared to those who do not.[177,178] For pediatric patients unable to use IV PCA, continuous infusions or intermittent IV administration of opioids is effective in providing postoperative analgesia.[179] Although respiratory depression may occur with opioids regardless of the route administered, clinically significant respiratory depression in pediatric patients is relatively uncommon.[176] Unlike adults, pediatric patients do not appear to exhibit multiple episodes of clinically significant oxygen desaturation postoperatively when treated with neuraxial, IV, or intramuscular opioids.[180] Use of nonopioid analgesic agents, such as NSAIDs or acetaminophen, may improve overall analgesia, reduce the amount of opioid used postoperatively, and decrease some opioid-related side effects such as postoperative nausea and vomiting.[181] For rectal administration of acetaminophen postoperatively, a larger dose (40 mg/kg followed by three doses of 20 mg/kg at 6-hour intervals) than that previously recommended may result in appropriate serum analgesic levels.[182] In addition, other analgesics such as ketamine and tramadol may be considered as adjunct analgesic drugs for the treatment of postoperative pediatric pain in specific clinical situations.[84,183]

Peripheral and neuraxial regional analgesic techniques are commonly used and effective for acute pain management in pediatric patients. The use of ultrasound-guided regional analgesic techniques has been described and may further increase the use of efficacious regional analgesic techniques for pediatric postoperative pain management.[184] One of the more frequently used techniques is epidural analgesia, which can be delivered as a single dose or by using a continuous-infusion catheter technique. The catheter may be inserted (typically using general anesthesia) anywhere along the epidural space (e.g., thoracic, lumbar, caudal), but the caudal approach seems to be the most common technique because the catheter can be easily advanced cephalad to the appropriate dermatome. Local anesthetics or opioids, or both, can be administered through the epidural catheter or needle to provide effective postoperative analgesia. Although epidural (caudal) analgesia may be safely administered to neonates, the clinician should recognize that the maximal continuous infusion dose is probably smaller than that in older children because of lower levels of α_1-acid glycoprotein (which binds local anesthetics) and diminished ability of the relatively immature liver to metabolize amide local anesthetics.[185] The addition of adjuvant drugs, such as clonidine, in the epidural infusion may enhance postoperative analgesia.[186]

Continuous epidural (caudal) analgesia may be used in the postoperative setting, and the infection rate associated with continuous epidural analgesia is extremely low despite the relatively high colonization rate.[125] In addition, continuous peripheral catheter techniques can be used effectively in pediatric patients. Regional analgesic techniques may be useful in providing analgesia for wound incision (e.g., herniorrhaphy or orchiopexy), thoracotomy, and orthopedic procedures.[187] Local anesthetics may also be administered topically to provide analgesia. Despite a lack of data comparing outcomes for regional analgesia versus systemic opioids in the pediatric population, some evidence suggests that the use of epidural analgesia is associated with improvement in some outcomes such as earlier tracheal extubation, return of gastrointestinal function, and length of hospital stay.[188] Finally, other modalities such as acupuncture may be a potentially useful adjunct for the treatment of pediatric postoperative pain, although further large scale randomized, controlled clinical trials are needed to define the role of these modalities in the treatment of pediatric postoperative pain.[189]

OBESITY, OBSTRUCTIVE SLEEP APNEA, AND SLEEP

Patients with obesity and OSA may be at a more frequent risk for postoperative complications. Obesity and OSA are separate disease states, but there is some association between the two because OSA occurs in a relatively higher percentage of obese than nonobese patients. Yet, the optimal postoperative analgesic and monitoring regimen for patients with OSA is not clear. Data suggest that sleep is disrupted in the immediate postoperative period and may influence postoperative morbidity and patient-oriented outcomes.

Obesity is defined as a body mass index (BMI) of greater than 30 kg/m^2, with morbid and supermorbid obesity defined as a BMI of greater than 40 and 60 kg/m^2, respectively. The prevalence of obesity has continued to increase over the past decades to epidemic proportions (including children and adolescents) and is similar across the different ethnic, educational, and income groups.[190-192] Patients with OSA may be at higher risk for pulmonary hypertension, cardiomyopathy, systemic hypertension, and possibly myocardial infarction than their non-OSA counterparts. The pathophysiology of airflow obstruction is related primarily to upper airway pharyngeal collapse, including the retropalatal, retroglossal, and retroepiglottic pharynx, during sleep, especially during rapid eye movement sleep. During these obstructive episodes, OSA patients may exhibit hypoxia, bradyarrhythmias or tachyarrhythmias, myocardial ischemia, abrupt decreases in left ventricular stroke volume and cardiac output, or increases in pulmonary and systemic blood pressure.

Based on our understanding of the pathophysiology of OSA, postoperative pain management can be difficult in this population. Patients with OSA may be at an increased risk for respiratory arrest.[193] Although it is not clear whether OSA will increase the risk of postoperative hypoxemia when compared to other morbidly obese subjects without OSA, morbidly obese subjects (with or without OSA) may experience frequent oxygen desaturation episodes in the postoperative period even with the use of supplemental oxygen. Use of sedative doses of benzodiazepines and opioids may result in frequent hypoxemia and apnea, which may be especially dangerous in OSA patients. Use of nonopioids (e.g., tramadol, dexmedetomidine) or an opioid-sparing technique may limit some of the respiratory-related events postoperatively. Avoiding respiratory depressants by optimizing the use of NSAIDs, nonopioid adjuvants (including clonidine, ketamine, dexmedetomidine), complete avoidance of benzodiazepines, epidural analgesia with a local anesthetic-based regimen, peripheral nerve blocks, and local infiltration techniques may attenuate the risk for respiratory depression and arrest.

The American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Obstructive Sleep Apnea created guidelines that include recommendations for postoperative analgesia in patients with OSA.[191] Although the consultants acknowledged that the conclusions regarding postoperative analgesic options were based on insufficient literature evaluating the effects of various analgesic techniques, the presence of equivocal literature regarding the use of epidural opioids versus intramuscular or IV opioids in reducing respiratory depression, and insufficient literature regarding the addition of a basal infusion to systemic patient-controlled opioids, the consultants nevertheless recommended that regional techniques rather than systemic opioids be used in an attempt to reduce the likelihood of adverse outcomes in patients at increased perioperative risk from OSA.[194] In addition, the consultants recommended the exclusion (vs. inclusion) of opioids from neuraxial postoperative analgesia to reduce perioperative risk and the use of NSAIDs to reduce adverse outcomes through their opioid-sparing effect. The consultants were equivocal regarding whether avoiding a basal infusion of opioids in patients with OSA reduces the likelihood of adverse outcomes.[194] Unfortunately, randomized clinical trial data are lacking to provide definitive high-quality evidence-based recommendations for the provision of postoperative analgesia to OSA patients.

INPATIENT PAIN SERVICES

“Acute pain services” or “acute pain medicine” is not synonymous with regional anesthesiology pain services (RAPS) or PPS; each term describes a different role and the terminology can be confusing to other physicians and surgeons in the healthcare system. An APS/APM is a more comprehensive service than a PPS. APS/APM take care of all inpatient acute pain issues including perioperative pain as well as medical pain and acute-on-chronic pain such as sickle cell disease, pancreatitis, and acute exacerbations of inflammatory bowel disease or other condition requiring medicinal or catheter-based techniques for pain relief. A PPS takes care of only perioperative pain patients with the same techniques, and RAPS addresses only those patients with a catheter placed by an anesthesiologist for postoperative pain. Which type of service each hospital has depends greatly on the local expertise, the local financial resources available, and the patient population. Chronic pain services developed from the needs of patients in hospitals with the less comprehensive or RAPS/PPS-type of pain service because these services have a very restricted treatment group. As academic regional anesthesiologists have expanded their role to include that of the perioperative pain physician or the APM physician, they have developed services that encompass all inpatient pain concerns, and the role or necessity of the primarily outpatient pain medicine physician (commonly referred to as the chronic pain physician) in the hospital has been reduced.

Although there are several models for the development of APS/APM, the key organizational aspects are similar (Box 81.2). Development and maintenance of APS/APM requires commitment and financial support at the national and local (institutional and departmental) levels. In the United States, there is a dichotomy at the national and third-party payer levels between the requests for improved inpatient pain control, along with the introduction of practice guidelines or expanded roles for APS, and decreased reimbursement for the provision of such services. Because there is a substantial financial burden associated with the establishment of an inpatient pain service, large-volume or larger hospitals may be more likely to have these services and access to more high-tech analgesic techniques such as regional analgesia. Formal inpatient pain services using postoperative pain protocols are more likely to be present in academic/teaching hospitals when compared to nonteaching hospitals. Whether inpatient pain services actually improve outcomes is unclear. Two earlier systematic reviews have examined the impact of APS on patient outcomes,[7,195] and although both systematic reviews suggest that the introduction of APS is associated with a decrease in pain scores, the effect of APS on the incidence

BOX 81.2 Organizational Aspects of an Inpatient Pain Medicine Service

Educational Activity

Anesthesiologists
Residency-fellowship teaching (if applicable)
Health insurance carriers
Hospital administrators
Nurses
Patients and families
Pharmacists
Surgeons

Administrative Activity

Economic issues
Evaluation of equipment
Human resources: pain service personnel, administrative-secretarial support
Institutional administrative activity
Quality improvement and assurance
Research (if applicable)

Nursing

Continuing education and in-service training
Defining of roles in patient care
Nursing policies and procedures
Pain service nurse (if applicable)
Quality improvement and assurance

Documentation

Hospital policies and procedures
Bedside pain management assessment flow sheet
Daily consultation notes
Educational packages
Protocol driven order-sets

of analgesic-related side effects (e.g., nausea, vomiting), satisfaction, and overall costs is uncertain. Despite the direct costs (e.g., personnel, equipment, medication) associated with managing an APS, there is no properly conducted pharmacoeconomic study available to examine the cost-effectiveness (or lack) of an APS. Use of postoperative epidural analgesia in the context of APS may decrease the cost of patient care through shorter intensive care unit stays and a decreased rate of complications.[13] Nevertheless, an RCT comparing an anesthesiologist-led, nurse-based APS group with PCA versus a control group with systemic boluses of opioid analgesia noted that an APS was likely to be cost effective when the role of the APS was extended to a specific group of major surgical procedures.[196] A dedicated inpatient pain service allows anesthesiologists to extend their presence in the field of perioperative medicine, although there is no universal agreement on how to provide these services in a financially viable way.[195] This represents one of the numerous challenges that face the development of these services. If that service becomes valuable to the local medical scene, financial support will almost always follow in one way or another. As inpatient APM services continue to evolve into comprehensive inpatient pain medicine services, there is less need for a separation of acute and chronic pain services for inpatient pain care. The elimination of this duplication and the indeterminate roles of service(s) can reduce costs and improve continuity of patient pain care. Despite the costs associated with implementation of a comprehensive inpatient pain service, these services provide a valuable resource at the individual, institutional, and societal levels. With the development of the APS/APM, we now have different training goals for the traditional regional anesthesiology fellowships, including more formal education in chronic pain conditions and management of these conditions while the patient is hospitalized with acute illness. This would involve education on the medical management of these conditions in the short-term, maintenance of the patient's long-term therapies, and knowledge on how these interact with acute pain management.

With skills in regional anesthetic techniques and knowledge of the neurobiology of nociception and the pharmacology of analgesics and local anesthetics, as well as specialty education in the treatment of acute and chronic pain conditions, anesthesiologists are recognized leaders in perioperative pain relief and the development of APS. Provision of inpatient analgesia, along with other services such as critical care medicine and preoperative evaluation, is highly compatible with the emerging identity of anesthesiologists as perioperative physicians and enhances the role of anesthesiologists as valued consultants outside the operating room.

Acknowledgment

The editors, publisher, and Drs. Robert W. Hurley, Nabil M. Elkassabany, and Christopher L. Wu would like to thank Dr. Jamie D. Murphy for her contribution to this chapter in the prior edition of this work. It has served as the foundation for the current chapter.

Cognitive Dysfunction and Other Long-Term Complications of Surgery and Anesthesia

LISBETH EVERED, DEBORAH J. CULLEY, and RODERIC G. ECKENHOFF

KEY POINTS

- Postoperative cognitive concerns have been voiced by older patients, their families, and caregivers for over a century, and more recently documented with objective testing.
- The term postoperative cognitive dysfunction (POCD) is neither recognizable by the general medical community nor sufficiently granular to cover the spectrum of perioperative cognitive disorders. It will be replaced by a DSM-5-motivated nomenclature, which will include postoperative delirium.
- The new Perioperative Neurocognitive Disorder (PND) nomenclature will require subjective complaints in addition to objective testing and assessment of daily function.
- Objective testing can take many forms, and can be variously analyzed to establish if a decline has occurred.
- Cognitive screening in older adults should be included in preoperative consultations, and informed consent discussions should include PND.
- PND is the most common perioperative complication in older adults, and the strongest risk factors for PND are advanced age and prior cognitive disorder.
- Few intraoperative parameters or drugs are associated with PND, although some EEG metrics predict delirium and PND in a few studies.
- Many mechanisms for PND have been proposed and tested in preclinical models. Neuroinflammation induced by the surgery in the setting of a vulnerable or "primed" brain has the most support at this time.
- Other than cognitive screening, validated imaging or biofluid biomarkers are not yet available for either risk stratification or disease monitoring.

Introduction

Anesthesia and surgery have been associated with cognitive changes in older adults for more than 100 years,[1] but these observations were largely anecdotal until the International Study of Post-Operative Cognitive Dysfunction (ISPOCD) was undertaken in the late 1990s.[2] Since then, there has been intense investigation and interest in all aspects of "POCD," ranging from mechanistic to therapeutic, rodent to human. This chapter hopes to capture this breadth of investigation in a manner that informs the clinician and peaks the interest of the investigator. At the outset, we emphasize problems with the existing definitions and terminology, and present recommendations for a new nomenclature and diagnostic criteria. We will then present and discuss the details related to both subjective and objective metrics of cognitive decline. Of perhaps greatest interest to clinicians are the pre- and intraoperative risk factors associated with cognitive decline, and if the perioperative management can be adjusted to mitigate the risk. Finally, we review and discuss potential mechanisms underlying the various postoperative neurocognitive disorders (NCDs), both related to the anesthetic management as well as the surgery and associated comorbidities. The chapter is thoroughly referenced, but this field is advancing rapidly, and thus it is inevitable that some current literature is not represented.

Nomenclature, Diagnosis, and Measurement

NOMENCLATURE

The ISPOCD group coined the term postoperative cognitive dysfunction (POCD), which reflected an objectively measured decline in cognitive function that typically persists beyond the period expected for normal recovery from the physiological and pharmacological effects of anesthesia and surgery.[3] When patients presenting for anesthesia and surgery are identified with cognitive impairment at baseline, this has been referred to as preexisting cognitive impairment (PreCI).[4]

TABLE 82.1 Constructs Previously Used to Define Cognitive Change Associated with the Perioperative Period and the Recommended New Nomenclature

Time Period	Previous Nomenclature	Old Criteria	New Nomenclature	New Criteria
OVERARCHING TERM: PERIOPERATIVE NEUROCOGNITIVE DISORDERS (PND)				
Preoperative Baseline	Preexisting cognitive impairment (PreCI)	≥2 SD below norms on ≥2 tests	Mild/Major NCD	NCD criteria, DSM-5: 1 to <2 SD (mild) or ≥2SD (major) below norms or controls in ≥1 cognitive domain *Plus:* Subjective complaint, *and* IADLs (preserved for mild NCD and declined for Major NCD)
Acute postoperative	Postoperative delirium (POD)	DSM-5	Delirium (postoperative) (POD)	DSM-5
1-30 days postoperatively	Postoperative cognitive dysfunction (POCD)	≥1.96 SD below controls on ≥2 tests	Delayed neurocognitive recovery	NCD criteria, DSM-5
30 days-12 months postoperatively	Postoperative cognitive dysfunction (POCD)	≥1.96 SD below controls on ≥2 tests	Mild NCD (postoperative) Major NCD (postoperative)	NCD criteria, DSM-5
New diagnosis beyond 12 months postoperatively	Postoperative cognitive dysfunction (POCD)	≥1.96 SD below controls on ≥2 tests	Mild NCD Major NCD (unless not a new diagnosis)	NCD criteria, DSM-5

IADLs, Instrumental Activities of Daily Living; *NCD*, neurocognitive disorder.

Postoperative delirium (POD) refers to a form of acute cognitive disruption characterized by inattention, a fluctuating course, and cognitive disturbance, and is diagnosed according to the Diagnostic and Statistical Manual for Mental Disorders, version 5 (DSM-5).[5] Delirium in the community conforms to the same definitions and criteria. In contrast to POD, which conforms to the criteria for delirium diagnosed in any situation, POCD and PreCI have been confined to the field of perioperative medicine research where they have been historically defined by objective criteria with no attention given to subjective or functional criteria. In contrast, cognitive impairment and decline diagnosed in the general community conforms to either DSM-5 definitions and criteria, and/or the National Institute of Aging-Alzheimer's Association (NIA-AA) definitions, all of which require a subjective component and an assessment of activities of daily living (ADL). The NIA-AA terms Mild Cognitive Impairment (MCI[6] and dementia[7]) are more familiar than the DSM-5 terms (mild and major NCD), but the definitions and criteria roughly map onto each other.

The NIA-AA nomenclature is more granular, making provisions for the inclusion of biomarkers (biochemical and imaging). This is currently useful for research purposes, but is likely to apply to clinical scenarios in the future. In addition to the subjective complaint and functional criteria, another important difference between DSM-5/NIA-AA and POCD/PreCI has been the objective criteria applied. Although variable, many POCD/PreCI studies require a decline of 1.96SD below controls on two or more tests from a battery of 8-10 neuropsychological tests. Mild NCD and major NCD require 1-2SD and ≥ 2SD, respectively, below controls/norms in only one cognitive domain.

These differences, combined with the variability of POCD criteria (and timing) prompted an international multidisciplinary group to consider a new nomenclature for POCD.[8] Not only would diagnostic standardization facilitate further research in the area, but it would allow effective communication between clinicians at a clinical level. This new nomenclature recommends "perioperative neurocognitive disorders" (PND) as an overarching term for cognitive impairment or change, including delirium, identified in the perioperative period. Constructs previously used to define cognitive change associated with the perioperative period are discussed below with the recommended new nomenclature (Table 82.1).

Preexisting Cognitive Impairment

PreCI was used to refer to objectively assessed cognitive impairment that is observed in patients at baseline (compared to population norms). This is a preoperative assessment of impairment and should be considered in terms of cognitive impairment that might be coincidentally identified in the community and not just in terms of impending anesthesia and surgery. Hence, it is recommended that the term PreCI be replaced by mild NCD (MCI) or major NCD (dementia).

Delirium

POD should be recognized as a specific category consistent with DSM-5 terminology if the patient is in the immediate postoperative period and other specific causes have been excluded. The reported incidence of POD in the elderly is highly dependent on how it is diagnosed and screened. The most widely used and validated tool is the Confusion Assessment Method (CAM) (Box 82.1)[81]. The term *postoperative* refers to a specific and known temporal association with anesthesia and surgery, noting that surgical procedures occur annually in approximately 30% of individuals aged 65 years or more. POD is therefore defined as delirium which occurs in hospital up to 1 week postprocedure or until discharge, and which meets DSM-5 diagnostic criteria.

Postoperative Cognitive Dysfunction

POCD has been used in research studies to describe an objectively measurable decline in cognitive function at intervals from one day to 7.5 years after surgery.[9-11]

BOX 82.1 **Confusion Assessment Method**

Must include both:
A. Acute onset and fluctuating course
B. Inattention
And one of either:
C. Disorganized thinking
D. Altered level of consciousness

Significant heterogeneity around the definitions, time points for assessment, and criteria for POCD has resulted in widely varying results. As stated above, POCD does not require a subjective complaint or evidence of functional impairment, while the DSM-5 requires both. Thus, the major differences between POCD and NCD are the requirement for a cognitive concern, evidence of daily function, and the requirement for an objective decline in only one cognitive domain in the latter.

Cognitive Concern

The subjective cognitive complaint could be reported by the individual, family member, caregiver, or clinician. It is unlikely in the early postoperative period that a patient or an informant would be able to make an accurate assessment of subtle cognitive decline. Therefore, while assessment for NCD after discharge but prior to full recovery may be technically possible, the clinical relevance of its attribution would be unclear. Therefore, the term "delayed neurocognitive recovery" (dNCR) is recommended for this interval. This term should be used up to 30 days after the procedure, when recovery from most surgery and hospitalization should have occurred. The diagnostic criteria for NCD may be applied, but the outcome if impaired would be dNCR. It is possible that high functioning individuals may report cognitive concerns without objective evidence of decline. Because the subjective report from the participant, informant, or clinician is an essential element of diagnosing a PND, this may still be considered dNCR, and considered in the context of each individual case for clinical interpretation.

Activities of Daily Living Assessment

Assessment of daily function is an essential element of classifying mild and major NCD. This is achieved using an appropriate tool to measure ADL, which are everyday *personal care* activities that are fundamental to caring for oneself and maintaining independence. To detect more subtle declines in function, Instrumental Activities of Daily Living (IADLs) are used, which include activities like shopping, driving, and managing finances. For mild NCD (MCI), ADLs are maintained, while for major NCD (dementia), a decline is required.

Objective Testing

According to DSM-5[5] and our recommended PND terms,[8] mild NCD (postoperative) requires a 1 to <2 SD decline in cognitive testing compared to controls or norms, and major NCD (postoperative) requires a decline of 2 or more standard deviations on one or more cognitive domains (complex attention, executive function, learning and memory, language, perceptual-motor, or social cognition)[5] using an appropriate neuropsychological assessment. Neither the DSM-5 nor the NIA-AA criteria for objective testing specify individual neuropsychological tests, nor the number of tests required in a battery. It is important to note that this refers to psychometric assessments that objectively assess specific cognitive domains, *not to the use of screening tools* such as the Mini-Mental State Examination (MMSE) or the Montreal Cognitive Assessment (MoCA). While useful for preoperative risk assessment, these brief screening tools do not have the sensitivity to assess change in specific cognitive domains.

Thirty days after surgery, the term mild NCD (postoperative) (postoperative MCI) or major NCD (postoperative) (postoperative dementia) should be used instead of dNCR. The "postoperative" modifier should be used as long as the criteria are met, and as long as first diagnosed prior to 12 months postoperatively. If first noticed or diagnosed 12 or more months following surgery, the postoperative modifier is not used.

MEASUREMENT AND DIAGNOSIS OF PERIOPERATIVE NEUROCOGNITIVE DISORDERS

Historically, a diagnosis of POCD has relied only on an objective assessment of decline using a battery of neuropsychological tests that cover many cognitive domains (e.g., executive function, memory, attention, visuospatial, psychomotor, and language). In most studies, very conservative cut-points were applied (e.g., 1.96 standard deviations below controls on two or more tests out of a battery of 8-10). These research applications contrast sharply with the simple objective criteria required for mild NCD (postoperative) or major NCD (postoperative) as described above, and are described in detail elsewhere.[12]

Assumptions Underlying Assessment of Postoperative Cognitive Dysfunction/ Perioperative Neurocognitive Disorder

Prospective studies investigating POCD usually assessed baseline cognition at a single time point only, often within days to weeks of the procedure. This makes three important and not necessarily valid assumptions. First, it assumes normal preoperative cognitive function, because screening was performed with a tool insensitive to cognitive impairment, such as the MMSE or MoCA. Second, a single time-point assessment assumes stable cognition. The third assumption is that results are reproducible, even without an intervention. Even if we assume that patients have stable cognition, it is unlikely that two consecutive assessments would yield the same results, due to a variety of intrinsic and extrinsic factors.

Cognitive Decline Outcome Criteria

There are several criteria that studies have used to define POCD in the past. These include the 1SD rule,[13] the 20% rule,[14] and the reliable change index (RCI).[15-17] Each has advantages and limitations, but the latter has the large advantage of incorporating the changes observed in a control group over a similar time period, largely to account for practice and time effects. Because the RCI can be related to a control group or normative data, it satisfies the DSM-5 criteria for NCD (postoperative).

Sensitivity. The number of tests directly impacts the sensitivity of the measure; for example, if the definition of POCD is a decline of 2SD in 2 tests from a battery of 8 tests, the probability of identifying a decline of 2SD in 2 tests from 10 tests is doubled to 0.10.[18] For the assessment of NCD, the DSM-5 only requires decline in one or more cognitive domains (complex attention, executive function, learning and memory, language, perceptual-motor, or social cognition), but does not recommend specific neuropsychological tests or a specific number of tests. Sensitivity can be improved by considering small declines across a number of tests, or a single very large decline in what is termed, "combined z-scores."[9,17]

While seemingly esoteric, the various methods of analysis can markedly impact the diagnosis of POCD/PND, highlighted by Keizer et al., who reported a POCD incidence of 10.5%, 31%, and 7.7% using the same test results with different methods of analysis (1SD definition, 20% definition and RCI, respectively).[19] Clearly, standardization will be required to interpret results across many studies.

More recently, computerized cognitive assessment batteries have been developed that avoid practice effects, offer easier administration, are quicker and standardized, and have the potential to overcome cultural and language difficulties. To date, however, computerized test batteries have received limited attention in POCD/PND research mainly due to a lack of relevant validation studies.

GROUP CHANGE VERSUS INDIVIDUAL CHANGE. Studies investigating POCD have variously used either individual or group change. Individual change refers to a dichotomous outcome of "decline" versus "no decline," whereas group analysis considers differences between groups on a continuous scale. Clinical studies typically then use statistics to compare an *a priori* primary outcome between two groups to test whether any observed difference is due to chance. But this approach misses important individual information within each group. In particular, the individuals who decline the most may be a small fraction of the group, but arguably are the most critical to consider. Some individuals may even demonstrate cognitive improvement, due to correction of underlying pathology and improved function (e.g., reduction in pain, improved mobility, improved ADL). Statistics that simply average these groups together will miss these important individual changes (Fig. 82.1), which might be due to identifiable and perhaps correctable factors.

Issues Associated With Repeated Testing

Serial neuropsychological testing is important to reliably assess the trend over time; however, repeated testing may introduce several sources of error, such as reliability, floor/ceiling effects, and practice effects. It is unclear if practice effects can be eliminated, as such effects can be observed as far out as 2.5 years. Individual (e.g., age, sex, culture, language, education, comorbidities, baseline cognitive function) as well as perioperative factors (anxiety, medications, pain, etc.) may also modulate the effect of repeated testing. Other strategies to improve reliability include parallel test versions and the use of control groups (*vide supra*). The major concern with control groups is selecting a well-matched one. It is generally desirable to match for comorbid conditions, even including the need for surgery, to evaluate the effect of the surgery itself.

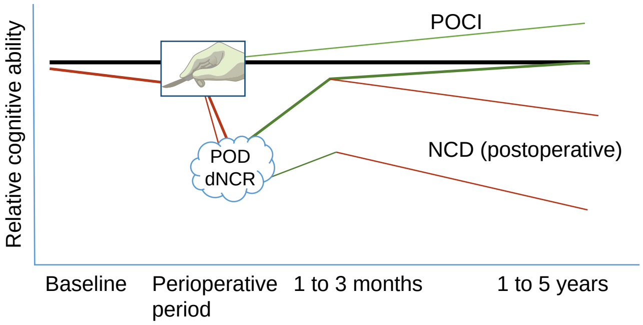

Fig. 82.1 Perioperative cognitive trajectories. Perioperative patients come into surgery having either a stable *(black)* or declining trajectory of cognition *(red)*. After surgery, the majority are unchanged *(black)*, with a small fraction showing postoperative cognitive improvement (*POCI, green*). Some postoperative patients have an acute decline into POD or dNCR, from which most recover *(green)*. A fraction of these will decline again later, perhaps matching their preoperative trajectory. The bottom red trajectory is meant to indicate that a very small fraction of perioperative patients never fully recover, and assume a steeper downward trajectory than if they had not had surgery. Thickness of line is intended as a rough reflection of probability of following the indicated trajectory. Other trajectories are possible. *dNCR*, Delayed neurocognitive recovery; *NCD*, neurocognitive disorder; *POD*, postoperative delirium.

Summary

Patient complaints of cognitive dysfunction after anesthesia and surgery have been reported for over a hundred years, but only recently studied systematically. These studies have included a wide variety of definitions, but all leading to the same provincial diagnosis, POCD. Recent work has standardized definitions and nomenclature for the clinical diagnosis of what are now called the PNDs, to make these consistent with that in the general population, and to recognize differences in magnitude and timing. Finally, we offer a more research-oriented framework for objective study in the future.

Risk Factors, Informed Consent, and Perioperative Management

RISK FACTORS

Multiple studies have investigated risk factors for the development of postoperative NCDs, with the most commonly cited being advanced age, a history of PreCI, and type of surgical procedure.[20,21] Other factors include a prior history of delirium, frailty, psychotropic medications, ASA physical status, number of medications, impairments in IADLs or ADL, and smoking.[22-25] PND is the likely combination of patient vulnerability along with the risks of the surgical procedure and its related complications that enhance the risk for the development of POD and potentially POCD. While many of these risk factors such as age and a prior history of delirium are not modifiable, there is growing interest in identifying modifiable risk factors and the use of multidisciplinary teams combined with prehabilitation to decrease the risk of developing PND.[26-29] Moreover, there has been growing interest in whether genetic risk factors, specifically the apolipoprotein-Ee4 genotype, are associated with the development of either POD or PND. Studies performed to date suggest that the presence of apolipoprotein-Ee4 genotype is not associated with the development of POD, but the data are less clear for other forms of PND, with some studies suggesting that it is, or is not, a predictor for the development of both dNCR and NCD (postoperatively).[30-36]

INFORMED CONSENT

It is currently uncommon that older adults are informed of their risk of PND in the consent process, despite clear evidence that PND is more common than most complications of which patients are routinely informed. However, informed consent is difficult to obtain in older operative patients because of a high prevalence of unrecognized MCI in this population. Among community-dwelling elders, as many as 70% may have some degree of cognitive impairment,[37] although the prevalence appears to be lower for those presenting for elective surgical procedures.[4,21] Preexisting MCI confounds their ability to understand the complex anesthesia and surgical procedures and risks, but also their risk for the development of subsequent NCDs. One must also remain cognizant that there may be substantial risks of forfeiting a surgical procedure that may be of benefit. While it is beyond the scope of this discussion to describe the entirety of the informed consent process, at a minimum, all older patients consenting for anesthesia care should clearly understand and actively participate in discussions about their risks and be capable of understanding the information provided about the planned management and potential adverse outcomes, including the risks of postoperative NCDs.[38-40]

PREOPERATIVE MANAGEMENT

Older patients often have geriatric syndromes that are not considered to be a part of the routine preoperative evaluation, yet are associated with an increased risk for the development of PND. For example, the risk of developing delirium is significantly increased in patients with preoperative cognitive impairment, frailty, functional impairment, depression, and among those taking certain psychotropic medications.[41] Accordingly, the American College of Surgeons together with the American Geriatrics Society have developed guidelines for the perioperative evaluation of older surgical patients that are relevant to the development of PND, including an assessment of preoperative cognitive performance, depression, functional status, frailty, and a review of prescription and over-the-counter medications, in order to identify those associated with a risk of PND. In the presence of these risk factors, the perioperative physician should consider referral to either a primary care physician, geriatrician, or mental health specialist for optimization or prehabilitation prior to the surgical procedure.[28] Identification of patients at highest risk for the development of PND may enhance patient-centered outcomes by providing patients and their families with a better understanding of their perioperative course and allow practitioners an opportunity to deploy resources to those at highest risk.

Intraoperative Management

TYPE OF ANESTHESIA

Researchers and clinicians have widely debated whether regional anesthesia is preferable to general anesthesia in suitable surgical cases for the prevention of PND. For all forms of PND, including POD, it is intuitive that regional anesthesia will be preferable, as general anesthesia targets the CNS, and data now suggest that deep anesthesia is associated with a higher incidence of NCDs. However, most studies have been unable to show differences in the risk of either POCD or POD following surgery under either general or regional anesthesia.[42-45] There are a number of potential reasons for this lack of difference. One is that regional anesthesia is often accompanied by sedation at levels comparable with general anesthesia based on processed electroencephalogram monitoring.[46] However, even in the few studies that have limited or randomized sedation during regional anesthesia, little difference was found.[45] This is the basis for the current hypothesis that most forms of PND, including POD, are the result of the surgery itself, combined with preexisting vulnerabilities.

DEXMEDETOMIDINE

Studies have demonstrated that dexmedetomidine, as compared to benzodiazepines and/or propofol for sedation, decreased the incidence of delirium in the intensive care unit. This observation has led to investigations of dexmedetomidine as an intraoperative adjunct to either regional or general anesthesia in older patients.[47,48] The majority of these studies have found that perioperative dexmedetomidine was associated with a lower prevalence of PND as compared to propofol in both cardiac and noncardiac surgery patients.[49-52]

However, it remains unclear whether the reduction in PND is due to the pharmacologic actions of dexmedetomidine itself or simply less brain depression. There is a growing body of evidence that deep sedation or general anesthesia based upon EEG monitoring during a regional anesthetic is associated with a higher prevalence of PND as compared to lighter levels of sedation or general anesthesia.[53] In other words, it may be the state of the brain (and duration) that is responsible for a lower risk of PND, rather than any specific effect of the drugs themselves.

KETAMINE

Ketamine is rarely used as a sole anesthetic, but it is frequently administered intraoperatively to reduce postoperative pain. Most studies performed to date have not shown that intraoperative administration of ketamine, despite its ability to decrease postoperative opioid requirements, decreases the incidence of POD and some studies suggest that it may increase it.[54-56] In addition, at least one study noted that intraoperative administration of ketamine may be associated with postoperative hallucinations and nightmares.[56]

INTRAOPERATIVE BRAIN MONITORING

There has been a growing interest in whether intraoperative management based on processed EEG or cerebral oxygen monitoring decreases the risk of either PND or POD. There is evidence to suggest that the use of the processed EEG to guide anesthetic management may reduce the risk of both, although the evidence is greater for POD.[57-59] Questions remain as to the mechanism, whether PND is a direct result of the anesthetic or its dosage, or the development of EEG burst suppression patterns. Evidence indirectly supports the latter, as the dosage of anesthetic being administered to the patients has not been rigorously correlated with the development of PND.[58,60] As there is little risk of EEG monitoring in most surgical procedures, some have recommended that EEG-based management be used to reduce the risk of PND in older surgical patients.

The evidence is less clear for the use of intraoperative cerebral oximetry to reduce the risk of PND. While some studies have suggested that higher perioperative cerebral oxygen saturation is associated with a lower risk of POD, therapeutic restoration of regional cerebral oxygen desaturation has not been shown to lower POD risk. Overall, the evidence for the use of cerebral oximetry for the prevention of POCD is greater than that for POD, although the majority of studies performed to date have been in the setting of cardiac surgery.[61,62] Taken together, the evidence makes it difficult to make a recommendation regarding the measurement of cerebral oxygenation during routine surgical procedures.

BLOOD PRESSURE CONTROL

There is currently significant interest in whether hypotension, hypertension, or blood pressure variability are associated with the development of PND, but the data are often difficult to interpret. Early studies that randomized patients to either high or low blood pressure management failed to find a difference in cognitive outcomes.[63] However, subsequent observational studies have suggested that intraoperative hypotension, hypertension, and blood pressure variability were each associated with the development of PND, as were vasopressor administration and postoperative hypertension.[64-67] While there is no clear evidence for what constitutes optimal blood pressure management in older surgical patients, maintenance of normal blood pressures without significant variability may decrease the risk of developing PND.

Postoperative Management

PAIN MANAGEMENT

The national opioid crisis has focused anesthesiologists' attention to the use of opioid-sparing techniques in the perioperative period. This is particularly relevant for older surgical patients, in that both postoperative pain and the administration of opioids have been associated with the development of POD. However, the outcomes from opioid-sparing pain management studies are often mixed.[55,68] For example, while regional analgesic techniques to manage postoperative pain are associated with decreased opioid consumption, their role for preventing the development of POD is less clear.[55,69-72]

As described above, perioperative administration of dexmedetomidine has been shown to decrease the development of POD in the majority of studies.[49] Contributing to this action may be that the α-2 adrenergic receptor agonist analgesic effects of dexmedetomidine decrease opioid requirements.[73] Interestingly, there exists little evidence on whether clonidine, another α-2 agonist, is associated with a reduction in POD risk in older surgical patients.[74] Similarly, early studies suggested that the perioperative use of gabapentin reduces the development of POD, but subsequent investigations have demonstrated that, despite decreasing opioid consumption, gabapentin administration did not reduce the development of POD, and may increase respiratory side effects.[75-78] Acetaminophen and COX2 inhibitors have also been suggested as a part of multimodal pain management strategy to reduce POD. While acetaminophen administration has been associated with a reduction in postoperative opioid utilization, it has not been associated with a reduction in POD.[79] In contrast, COX2 inhibitors have been shown to decrease pain severity, opioid utilization, and POD in patients greater than 60 years of age undergoing lower extremity joint replacement surgery. This provides hope that multimodal management of postoperative pain in elders will be associated with a decreased risk of POD, yet may be associated with increases in the costs of pain management.[68,80]

At this point, the effective strategy to reduce PND in older patients is nonpharmacologic—for example, assuring good sleep and nutritional hygiene, rapid mobilization, and early orientation to familiar aspects of their environment, such as family members. Older patients may need their glasses and hearing aids to facilitate orientation. It is also important to remove devices such as Foley catheters to avoid urinary tract infections, to avoid Beers' criteria medications, and to promote normal bowel function. One cannot know the success of these interventions without testing for POD using validated instruments like the CAM.[81] Without formal screening, many cases of delirium, especially the hypoactive type, go undetected.

If a patient is found to be delirious, the cause may be identifiable. For example, delirium might be due to unrecognized hypoxia, pneumonia, urinary tract infection, electrolyte abnormalities, urinary retention, fecal impaction, acute renal failure, hypoglycemia, and dysrhythmias. The medication record may reveal drugs associated with the development of delirium, which should be discontinued, if possible. Nonpharmacologic interventions might include a calm environment and reorientation tools such as the presence of a clock, calendar, family members and familiar items, and the removal of restraint devices. Pharmacologic interventions should be reserved for those who pose a threat to themselves or others, as these drugs may mask, rather than treat, delirium. Effective drugs include dexmedetomidine

TABLE 82.2 Summary of Pathways and Biomarkers

Mechanism	Anesthetic Effect Rank/Order	Biomarker (Type*)	Biofluid	Imaging
Amyloidopathy	Enhanced, Halo>Iso>Des>Pfl	Amyloid β_{1-42} (1) Amyloid β_{1-40} (1)	Plasma, CSF,	Yes, several; e.g. ^{18}F-florbetapir
Tauopathy	Enhanced, Iso>Pfl	Total Tau (1,2) Phospho-Tau (1,2)	Plasma, CSF,	Yes, several; e.g. ^{18}F-AV1451
Apoptosis, Necrosis, Lysis	Enhanced, Iso>Pfl	S100β (2) Neurofilament Light (NFL) (2) Neuron-specific enolase (NSE) (2) Total Tau (1,2)	Plasma, CSF,	MRI. Loss of cellular thickness and/or enlargement of ventricles.
Calcium Dysregulation	Enhanced. Iso>Sevo=Des>Pfl	None	None	None
Neuroinflammation	Various, Sevo/Iso enhanced or no effect. Pfl reduces.	Cytokines, (1,2) Chemokines, CRP (1,2) Prostanoids, (2) Resolvins (2)	Plasma, CSF, Urine	Yes, several; e.g. ^{11}C-PBR28

and haloperidol, but the adage of "start low and go slow" to avoid exacerbating the duration or severity of delirium should be adopted.

For patients who develop PND of any form, it is important to refer them to their primary care provider, geriatrician, or mental health expert, as evidence is beginning to suggest that POD and PND are predictors of subsequent cognitive decline.[82-84]

Mechanisms and Biomarkers

As reviewed above, numerous studies in patients have documented a variety of cognitive syndromes following anesthesia and surgery, most of which resolve in several weeks. These clinical studies have only identified age and preexisting cognitive disorders as consistent risk factors; other perioperative features, such as surgery duration, anesthetic management, and intraoperative physiology (e.g., hypotension, hypoxemia) have not been rigorously implicated. Because these associative studies in patients have not yet provided strong clues as to the underlying mechanism, investigators have turned to preclinical models in order to understand causation and thereby design potential interventions. We will first review these preclinical studies and the various pathways that have been implicated, and then discuss how various biomarkers can be used to test for these mechanisms in patients. It is important to point out that early in this exploration, the general anesthetic drug was implicated in a form of "neurotoxicity," and then a gradual shift occurred to view the surgery itself as the primary causation. In reality, it is likely that both, as well as other factors, are involved.

Although PND findings and complaints vary widely, there are similarities in both symptoms and risk factors with neurodegenerative disorders, such as Alzheimer disease. Thus, early studies examined the canonical disease pathways in either cellular/molecular systems and animals, both wild type and transgenic, and these studies then paved the way toward human studies. Three disease-associated pathways will be considered as contributing to PND: amyloidopathy, tauopathy, and calcium dysregulation. Finally, we will discuss neuroinflammation as the principle surgical contribution to PND, and then final common pathways to cellular death. It is essential to realize that biomarkers can be used in at least two principal ways. The first is for risk stratification if collected preoperatively and may not be directly involved in either surgery or anesthesia mechanistic pathways. The second is for detecting and following disease progression and is more likely to directly reflect surgery or anesthesia pathways. Some biomarkers can be used in both ways. These pathways and biomarkers are summarized in Table 82.2.

AMYLOIDOPATHY

The involvement of a small proteolytic fragment of the membrane protein amyloid precursor protein (APP) in neurodegeneration was strongly implicated from both pathological as well as genetic studies.[85] The pathognomonic feature of Alzheimer disease (AD), the senile plaque, contains considerable quantities of this peptide in a characteristic aggregated form, but data now suggest that plaques are a less toxic, sequestered form of the peptide; the neurotoxic forms are thought to be the more labile small (~dodecamers) oligomers of the amyloid β peptide.[85] These oligomers are produced at various rates over a period of decades prior to the onset of symptoms (Fig. 82.2), and are variously eliminated or sequestered into plaque, making a causal association with symptoms exceedingly difficult. In fact, the mechanism by which such small aggregates produce cytotoxicity is not at all clear, but may involve a detergent-like action whereby an amphiphilic peptide inserts into, and disrupts, cell membranes.[86] Despite being a pathognomonic feature of AD, imaging and cerebrospinal fluid (CSF) studies (discussed later) have demonstrated a poor relationship between amyloid β accumulation and cognitive loss.

CELL AND MOLECULAR STUDIES

Initial studies found that inhalational anesthetics like halothane enhanced the aggregation of amyloid β in the test tube, and that when combined with cells in culture, also enhanced the cytotoxicity of exogenously added

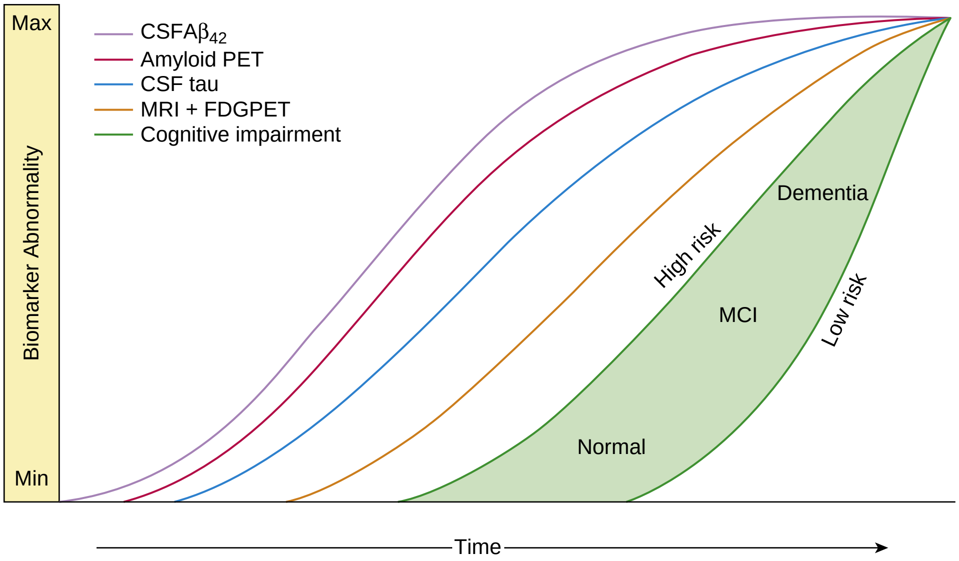

Fig. 82.2 A model of the progression of neurodegeneration and cognition. Cerebrospinal fluid *(CSF)* Aβ42 *(purple)* and deposition of amyloid on PET imaging *(red)* occur early and are then followed by elevations in CSF tau *(blue)* and probably tau aggregates on PET imaging (data not yet available). Neurodegeneration as measured by FDG PET and structural magnetic resonance imaging *(MRI, yellow)*, respectively, follow and precede functional changes such as Mild Cognitive Impairment *(MCI)* or dementia. By definition, all curves converge at the top right-hand corner, the point of maximum abnormality (not levels). The horizontal axis is time, which although highly variable, is on the order of decades. A vertical line drawn between normal and MCI approximates a large fraction of older patients presenting for surgery, which implies that many of our patients will have significant neuropathology at the time of their operation. (From Jack C, Knopman, DS, Jagust WJ, et al. Tracking pathophysiological processes in Alzheimer's disease: an updated hypothetical model of dynamic biomarkers. *Lancet Neurol.* 2013;12:207–216.)

amyloid β peptide.[87] Further studies found that the activity of the enzyme responsible for cleaving and releasing the amyloid β peptide, the β-acting cleavage enzyme, was enhanced by anesthetics like isoflurane, so that amyloid β *production* was also increased.[88] So even without exogenous amyloid β, this pathway was capable of causing apoptosis in cell culture systems. Moreover, isoflurane enhances the cytotoxicity of presenilin-1 mutations in cultured neurons.[89] Presenilin-1 is an important regulator of amyloid β production through effects on the γ-secretase complex, and the mutation in question upregulates this complex to amplify the production of amyloid β. Thus, it is clear that certain anesthetics intersect the amyloidopathy pathways at several points that result in exaggerated cytotoxicity.

There appeared to be variation in the degree that different anesthetics caused these effects. Halothane and isoflurane both caused substantial amyloid β production, aggregation, and cytotoxicity in cell culture.[87] On the other hand, desflurane caused less amyloid β production and apoptosis than isoflurane.[90] Perhaps most importantly, propofol at clinical concentrations (~1 uM) actually inhibited amyloid aggregation in vitro, and was without cytotoxicity in cultured cells.[87] Such rank-order effects are extremely important means of translating hypotheses to intact animals.

ANIMAL STUDIES

In early PND/POCD research, it was found that wild-type rats had impaired learning and memory after isoflurane anesthesia, and this was most apparent in older animals.[91] In addition to age, other vulnerabilities were introduced, such as human transgenes for AD, so that the amyloid mechanism could be explored in vivo. The Tg2576 animal contains the APP Swedish mutation that overproduces amyloid β and acquires cognitive deficits by 10 to 12 months of age. Several 2-hour exposures of aged animals to either halothane or isoflurane caused no further deficits in the already impaired learning or memory, but significantly increased the number and density of amyloid plaques in their brains.[92] Other rodent work, even in wild-type animals, has confirmed that anesthetic exposure (largely isoflurane) increases amyloid β levels in the brain.[93] Rank-order effects appear to be mostly retained, as halothane exposure increases amyloid plaque more than isoflurane,[92] and propofol had little effect, although this was in a different transgenic (3xTgAD) animal.[94]

HUMAN STUDIES

Amyloid β can be assayed in humans either postmortem or in the living by ELISA analysis of CSF, or PET imaging of amyloid β plaque. Low amyloid β in the CSF is consistent with AD pathology because the peptide is thought to be sequestered into plaque and less available for distribution into CSF. In addition, it might also reflect fewer active synapses, as the APP tends to be highly expressed in synaptic regions. Consistent with this, PET imaging that shows high density of amyloid-ligand binding is consistent with AD.[95] Studies have examined amyloid β preoperatively as a risk biomarker, or postoperatively as a marker of PND occurrence and progression. In the former case, it is relatively straightforward to get a sample of CSF when a spinal anesthetic is initiated. Analysis, however, is nontrivial, and should be conducted by standardized laboratories specifically established for this purpose. In one study, low CSF amyloid β predicted dNCR at 3 months postoperatively.[96] PET imaging with any of several amyloid β ligands can also be performed preoperatively for risk assessment. In a recent study of cardiac surgical patients, amyloid imaging was performed at 6 weeks and 1 year postsurgery. At neither time point was amyloid load associated with PND, but it was noted that amyloid load increased more between the two time points than in matched nonsurgical controls.[97] This result is directly analogous to the above animal study in that the increased amyloidopathy was not reflected in worse cognitive outcomes. The reasons are suggested by the mixed role that amyloidopathy represents, both reflecting the presence of, and the sequestering, of toxic oligomers, as well as the delay between this particular proteinopathy and neurodegeneration.

In addition to its use in risk prediction, the use of amyloid β as a marker of disease progression has been studied by several investigators, but in general for very limited periods (days). For example, in patients with lumbar drains in place for the operation and up to 2 days after surgery, repetitive sampling of CSF showed no significant change in the amyloid β.[98,99] An uncontrolled study in cardiac patients showed a significant decrease in CSF amyloid β 6 months after surgery, consistent with progressive amyloidopathy.[100] Finally, one study has shown that CSF amyloid β increases acutely after anesthesia and surgery, which may be consistent with prior data showing anesthetic-induced increases in amyloid β production.[101]

AMYLOIDOPATHY SUMMARY

It is now clear that anesthetics interact directly with the amyloid β pathways, and in a differential manner. The haloalkanes, exemplified by halothane, are the most provocative, predicting acceleration, whereas propofol has little effect. The critical in vivo data confirms these in vitro studies, but they also support the growing recognition that amyloidopathy is itself not temporally associated with cognitive ability, suggesting that amyloidopathy might not underlie the most prevalent form of PND, dNCR. It may, however, contribute to later forms of PND, such as mild or major NCD (postoperative), but the separation in time makes this association difficult to establish. Amyloid β will continue to be useful as a risk biomarker, especially if amyloid imaging or CSF is available preoperatively. Assays of amyloid β in blood have not reached the stage where they are considered sensitive and specific, but this is obviously a highly desired goal.

TAUOPATHY

The other major pathognomonic feature of AD (as well as various tauopathies) is the intracellular neurofibrillary tangle (NFT), now known to consist largely of tau protein. Tau is a microtubule-associated protein (MAP) that regulates microtubule stability and dynamics, both of which are critical for neuronal structure and intracellular transport.[102] Phosphorylation of tau at several sites causes it to detach from the microtubule, which if extensive, ultimately results in loss of microtubular function. Like amyloid, high concentrations of phosphorylated tau will begin to self-assemble into ordered fibrillary structures, which either directly cause further cell stress, or serve to isolate tau from the microtubule. In either case, both neurodegeneration and cognitive loss relate better to NFT prevalence (both by imaging and CSF levels) than does amyloid β, as it is thought to be a later event reflecting cell demise (see Fig. 82.2).[102] Release of tau from damaged cells is thought to enhance tauopathy in neighboring cells in a prion-like manner.[103] Release also deposits tau into the CSF and ultimately bloodstream, making it a useful biomarker of CNS stress/injury.

CELL AND MOLECULAR STUDIES

The effect of isoflurane has been evaluated in a few cell culture studies, and in each case, isoflurane (~2%) caused tau hyperphosphorylation, perhaps by upregulation of the associated kinase, GSK-3b.[104,105] Similarly, both propofol and dexmedetomidine caused tau phosphorylation in a neuronal cell line.[106,107] The mechanism appears to center around inhibition of the associated phosphatase, PP2A, either directly by hypothermia or direct anesthetic binding, or through inhibition of the PP2A-tau complex.

ANIMAL STUDIES

Early work showed that wild-type mice exposed to isoflurane had a dramatic increase in tau phosphorylation in their brains.[108] However, it was found that this was largely due to the extreme temperature sensitivity of the PP2A phosphatase, and the fact that the animals had been allowed to cool during the anesthetic.[108] Subsequent work has determined that a degree of excessive tau phosphorylation exists for several days after the anesthetic, even when animal temperature is carefully maintained.[109] A transgenic mouse that incorporates human genes associated with both amyloid and tau pathology also found that abdominal surgery under volatile anesthesia (desflurane) increased tau deposits, and that this was associated with learning and behavioral defects.[110] Interestingly, neither enhanced tau nor cognitive deficits were observed if propofol was used for the brief surgical procedure.[94]

HUMAN STUDIES

Clinical studies to date have been limited to assays of tau in CSF before and after surgery of various types. As stated previously for amyloidopathy, these studies often take advantage of the need for a subarachnoid catheter for the surgical procedure itself, but in some cases, repeated single CSF draws have been used. Results have been remarkably consistent. Total tau, but not phosphotau, is elevated after surgery, and it continues to rise for at least a day or two, when most of the sampling is terminated.[111] Presumably, this elevation of tau reflects CNS cellular damage, but the implications in terms of future cognition are not yet clear. It is important to note that PET ligands with affinity for NFT tau are now available, yet transsurgical studies have yet to appear in the literature. Sensitive and specific blood assays for tau and other injury biomarkers (neurofilament light, S100β) are now available, and a recent study shows elevations after surgery.[112] While far more convenient than CSF, blood is likely to be contaminated by peripheral tissue sources that are almost invariably damaged during surgery.

TAUOPATHY SUMMARY

The MAP tau is gaining much attention as a more proximal biomarker of CNS injury and neurodegeneration than amyloid β. The effect of anesthesia and surgery on tau is remarkably consistent across species and models, and suggests a form of CNS stress and injury in the immediate postoperative period. The upstream mechanism may reside in surgery-induced neuroinflammation (discussed later), but animal studies suggest that direct effects on tau phosphorylation may also contribute. Postoperative tau imaging studies hold substantial promise for defining the magnitude and time course of any surgery-induced CNS injury.

CALCIUM DYSREGULATION

Intracellular calcium is a critical cell function regulator, which, if excessively elevated, also leads to cell stress, apoptosis, autophagy, and necrosis. Calcium dysregulation has therefore been considered an important link between amyloidopathy/tauopathy and cell death, and has recently been proposed as a target for mitigation of neurodegeneration in disorders like AD,[113] although no trials are underway. The primary source of elevated calcium in neurons is thought to be the endoplasmic reticulum, released via the two major channels, the ryanodine receptor (RyR) and the inositol 1,4,5-trisphosphate receptor (InsP3R). An antagonist of RyR, dantrolene, is available and well known to anesthesiologists, but has two principle drawbacks. First, it is distributed only poorly to the brain with the usual parenteral administration, and second, it has the significant side effect of causing weakness due to effects on skeletal muscle. Dantrolene has been proposed as a treatment for AD.[114]

CELL AND MOLECULAR STUDIES

Electrophysiology and cell culture studies have shown that the volatile anesthetics enhance the opening of both the RyR and InsP3R, resulting in concentrations of intracellular calcium that activate apoptosis pathways.[115,116] These effects were not apparent in cell lines devoid of the $InsP_3R$, and were completely mitigated in normal cells treated with either dantrolene or an $InsP_3R$ antagonist, xestospongin-c. It is important to note that fairly high concentrations and long durations of volatile anesthetic exposure were necessary to produce these isolated cell effects, arguing against the in vivo relevance. Also, even higher concentrations of propofol were required to induce cytotoxic calcium levels, suggesting that potentially useful rank-order effects exist among the general anesthetics.

ANIMAL AND HUMAN STUDIES

There are only a few rodent studies that have demonstrated modest efficacy of chronic dantrolene in slowing cognitive decline and neurodegeneration,[117,118] but none to date on the efficacy of acute dantrolene in preventing POD or losses in memory or cognition. Perioperative human studies have not yet been reported.

CALCIUM SUMMARY

Calcium dysregulation is probably an important upstream event in anesthesia and surgery-induced cognitive decline, and yet has remained largely unstudied. While chronic dantrolene administration to slow the progression of AD might be considered implausible, the potential for acute, intraoperative use is attractive, especially given that the various formulations of dantrolene are already clinically approved, and that muscle relaxation during surgery is typically desirable.

NEUROINFLAMMATION

The consistent observation in animals that anesthetics alone induce only modest effects on pathology and cognition, and that more robust and consistent effects are produced in both when a surgical procedure is added, have led to the hypothesis that surgery-induced inflammation due to activation of the innate immune system is the principle contributor to PND. It is well established that surgery induces a classical systemic inflammatory response, triggered by damage-associated molecular pattern molecules, and propagated systemically by a variety of cytokines and chemokines. This inflammatory response is essential for wound healing and microbial defense, but can also exaggerate ongoing inflammatory processes in some individuals. In general, an intact blood-brain barrier (BBB) isolates the brain from significant inflammatory mediators and cells. But the BBB can become “leaky” in the elderly, and in those with preexisting neuroinflammation, so that the peripheral innate immune response can be more effectively transduced into the brain. This is the probable reason that age, preexisting cognitive decline, cardiovascular disease, diabetes, and frailty[2,84,119-124] are important risk factors for PND.

CELL AND MOLECULAR STUDIES

It is not possible to simulate surgery in cell culture systems, but attempts at pro-inflammatory influences have been combined with anesthetic exposure to understand the response of a variety of cell types. For example, a cultured microglia cell line had little cytokine response to sevoflurane and isoflurane (1 and 2 MAC) or to 1 or 2 ED_{50} of propofol. However, in the presence of low-dose lipopolysaccharide (LPS), robust cytokine responses occurred, which were amplified by exposure to the volatile drugs, sevoflurane more than isoflurane. On the other hand, clinical concentrations of propofol completely ablated the cytokine response to LPS.[125] While translation of cell culture results continues to be vexing, such studies will continue to be important to define molecular pathways contributing to cytotoxicity in specific cell types.

ANIMAL STUDIES

The literature contains numerous animal studies demonstrating the contribution of the inflammatory response to PND/POCD. For example, while subtle changes in behavior can be detected after anesthesia alone (typically

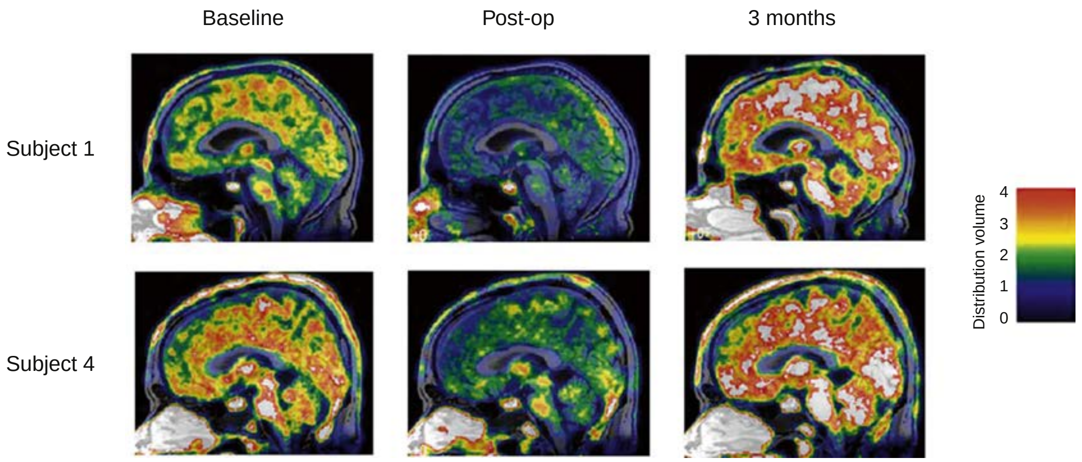

Fig. 82.3 Neuroinflammation imaging by PET after surgery. Two subjects undergoing abdominal surgery were scanned using a PET ligand that targets activated glia ([^{11}C]PBR28), generally thought to reflect the degree of immune activation in the brain. The baseline scan is before the operation and the "postop" scan, clearly showing immune suppression, is 4 days after the operation. At least in these two subjects, the "3-month" scan shows a degree of activation greater than baseline, which correlated with their cognitive assays. The suppression at 4 days may have followed an acute activation in the first day or two after surgery. (From Forsberg et al., *Ann Neurol.* 2017;81:572–582.)

isoflurane), the effects are considerably larger and longer lasting when combined with even a brief surgical procedure.[110,126,127] The effects of surgery-induced inflammation are further magnified in aged animals, metabolic syndrome animals, and in those with human disease transgenes, consistent with predictions above based on BBB disruption.[110,128-132] The cognitive effects are usually accompanied by more pronounced elevations in both peripheral and brain cytokine levels, and activation of astrocytes and microglia, disrupting the precise glia-neuron signaling axis.[133] Removal of pro-inflammatory components, either via cytokine antibodies (to IL-6 or TNFα) or antiinflammatory drugs (e.g., dexamethasone, statins), at least partially mitigates the effect of anesthesia and surgery on both behavior and pathology.[91,127,134,135] Because the pro-inflammatory effect is important for surgical recovery, some of these studies have noted that blocking these cytokines impairs wound healing. Thus, attention is shifting to modulation of inflammation via cholinergic pathways[130,136,137] or to the inflammatory resolution pathways, a complex mixture of specific cytokines (IL-4, 10) as well as small lipid mediators (resolvins). Two studies suggest efficacy of either exogenous cholinergic agonists or resolvin therapy to mitigate PND in rodents.[130,138] Finally, the bidirectional involvement of pain and analgesics in neuroinflammation is well appreciated, but the role in PND/POCD has not yet been systematically studied.

Although the evidence to date suggests that the anesthetic plays only a minor role in producing PND/POCD, the choice of drug may modulate the magnitude and duration of the neuroinflammatory response. For example, the cell culture studies suggested that propofol mitigated the effect of LPS on cultured microglia; accordingly, the use of propofol as compared to desflurane significantly reduced both the pathology and the behavioral effects of surgery in a transgenic animal.[94] In fact, one study suggested that chronic (subanesthetic) doses of propofol reduced the trajectory of decline in a model of murine AD.[139]

HUMAN STUDIES

As is becoming more the rule than the exception, the above rodent studies have only modestly translated to humans. This is undoubtedly a result of extreme variability in how patients are treated, and in the patients themselves. For example, most patients receive both propofol and a volatile agent; few receive a volatile agent alone. There is clear evidence of a peripheral pro-inflammatory effect of surgery, but of widely varying magnitude and duration.[140] Very consistent evidence for this peripheral immune response being mirrored in the CNS has also been reported. A series of studies sampled CSF before and out to 24 or 48 hours after surgery and measured several cytokines.[98,111,141,142] In each case, significant elevations in pro- and antiinflammatory cytokines were detected, which appeared to still be rising even at 48 hours. In addition, one study confirmed preclinical evidence of early changes in BBB integrity as indicated by an abrupt and transient increase in CSF/plasma albumin ratio after orthopedic surgery.[143] Interestingly, the nonrandomized study[98] found that total IV anesthesia was associated with lower CSF pro-inflammatory cytokines than inhalational anesthesia, although the larger randomized study could detect no difference between isoflurane- and propofol-based anesthetics. Again, it may be important to note that the isoflurane group also received propofol for induction in both studies, and that the dose-response relationship for antiinflammatory effects of this drug have not been established. A more recent PET imaging study noted that a marker of activated astrocyte microglia activation was significantly suppressed in patients 4 days after abdominal surgery and followed by an elevation at 3 months postsurgery that was associated with a reduction in cognitive capacity (Fig. 82.3).[144] These findings are consistent with earlier studies with the same PET probe in primates and humans, where an initial and rapid (4 hours) pro-inflammatory signal due to LPS was followed by depression at 22 hours.[145,146] Although difficult and expensive, more time points will be necessary in these biomarker studies to define the contribution of innate immunity to the cognitive outcomes.

Given an important role for inflammation, several studies have attempted mitigation with antiinflammatory medications, typically given in the immediate preoperative period or after induction of anesthesia. Two recent RCTs found dexamethasone reduced the inflammatory response and incidence of POCD[147,148] while two other clinical trials did not find a beneficial effect or even worse outcome.[134,149] A COX2 inhibitor (parecoxib) was found to reduce dNCR in elderly patients, as well as both pain and pro-inflammatory cytokines.[150,151] It is likely that optimal antiinflammatory dosages and timing have yet to be realized, or that emphasis needs to be shifted to enhancement of pro-resolution rather than blockage of pro-inflammation.

In addition, multi "omics" approaches are providing new insights into distinct immune-cellular responses after surgery that will likely inform better therapeutic strategies to prevent PND.[152]

NEUROINFLAMMATION SUMMARY

The evidence that surgery causes both peripheral and CNS inflammation is strong, but its mitigation has to date been largely unrewarding. In vitro studies suggest that the choice of general anesthetic drug might modulate the inflammatory response; however, this has yet to be borne out in patient studies. Future directions will involve deployment of appropriately timed antiinflammatory drugs or pro-resolution therapies in the perioperative setting.

Summary

The pathology and mechanisms are presented above as independent possibilities; however, it is likely that more than one, or all, are present simultaneously after surgery, especially in vulnerable individuals. For example, patients with preexisting MCI may already have both amyloidopathy and tauopathy, which has provoked a smoldering neuroinflammatory state (termed a "primed" state) prior to surgery (see Fig. 82.2). The super-imposed acute inflammatory response to surgery, together with any modulatory effects of the anesthetic, then interact with this primed state to acutely alter the effects of this pathology on synaptic, and therefore, cognitive function. This may be transient, resulting in dNCR, or might in turn accelerate the pathology itself, to result in further neurodegeneration and more durable NCD. This mechanistic work has provided the basis for biomarker development, and for a multimodal campaign on reducing the effects of anesthesia and surgery on the aging brain.

CLOSING COMMENTS

Interest in perioperative brain health issues in older adults is accelerating dramatically. Patients, their families, and caregivers, as well as perioperative providers and scientists, need to become familiar with the risk factors for, and consequences of, POCD/PND and the best practices to mitigate them. In this chapter, we have attempted to provide an up-to-date summary of most aspects related to POCD/PND, from mechanisms to therapy, but the reader desiring more detail should refer to the primary literature.

Acknowledgment

This chapter is a consolidation of content from two chapters in the 8th edition, Chapter 99, "Cognitive Dysfunction and Other Long-term Complications of Surgery and Anesthesia" and Chapter 15, "Perioperative and Anesthesia Neurotoxicity." Dr. Roderic Eckenhoff joins the editors and publisher to thank the following authors for their efforts: Drs. Lars S. Rasmussen, Jan Stygall, Stanton P. Newman, and Vesna Jevtovic-Todorovic. Their contributions have served as the foundation for the current chapter.

Critical Care Anesthesiology

ALEXANDER S. KUO, DUSAN HANIDZIAR, and J. MATTHEW ALDRICH

KEY POINTS

- Anesthesiologists have been key contributors to the field of critical care, both in the advancement of clinical practice and development of technology relevant to the field.
- Intensive care unit structure, staffing, and utilization varies considerably among developed countries. Studies generally show improved patient outcomes with "high-intensity" staffing models.
- Low-tidal-volume lung protective ventilation improves mortality for patients with acute respiratory distress syndrome (ARDS). Prone positioning is recommended in patients with severe ARDS.
- Open lung strategies that include optimization of positive end-expiratory pressure and recruitment maneuvers are of significant research interest and increasingly used in clinical practice. Study results, however, are mixed and do not clearly demonstrate improved outcomes.
- The Third International Consensus Definitions for Sepsis and Septic Shock (Sepsis-3), a new definition introduced in 2016, emphasizes the key elements of organ dysfunction and dysregulated host response.
- The Surviving Sepsis Campaign's guidelines and bundles promote early recognition, administration of antibiotics, and resuscitation with fluids and vasopressors.
- Hemodynamic resuscitation in shock requires careful evaluation of fluid responsiveness and assessment of end-organ perfusion. There is significant evidence that excess fluid administration can cause harm in critically ill patients.
- Cancer immunotherapy is a rapidly evolving field in oncology with significant toxicities, including cytokine release syndrome, that present new management challenges for intensivists.
- Point-of-care ultrasound is increasingly common in critical care practice but more research is needed to evaluate the impact on clinical outcomes.

Introduction

The history of critical care medicine is relatively brief, dating back to the middle of the previous century. During this time, the field has evolved considerably, with changing approaches to the management of mechanical ventilation, hemodynamic support, sedation, renal replacement therapy, and patient mobilization. Modern critical care is an exciting domain of medicine, with an increasing focus on interprofessional care, family engagement, and long-term outcomes. Outcomes no longer include only attention to survival and length of intensive care unit (ICU) and hospital stay, but also recognition of post-hospital impairments and the new described entity of Post-Intensive Care Syndrome.[1] This chapter begins with a brief overview of the history of critical care medicine, including the specific role of anesthesia intensivists. We will then discuss modern and future ICU structure and management, including focus on resource utilization, staffing and team design, costs, and outcomes. The remainder of the chapter will discuss essential areas of management, including ICU Liberation/A-F Bundle, respiratory failure, shock and hemodynamic support, sepsis, and critical care in oncology.

HISTORY OF CRITICAL CARE MEDICINE AND THE ROLE OF ANESTHESIA INTENSIVISTS

Critical care medicine and the development of the first ICU is often credited to Bjorn Ibsen, a Danish anesthesiologist, in 1952.[2,3] Dr. Ibsen, who was trained in anesthesia at Massachusetts General Hospital, was consulted to help in the care of a 12-year-old girl with poliomyelitis (polio) and respiratory failure. He instituted the approach of manual positive pressure ventilation via a tracheotomy and then applied this to dozens of patients throughout the course of the polio epidemic in Copenhagen. Equally important, Dr. Ibsen implemented the approach of caring for groups of patients with respiratory failure in a dedicated location, thus creating a version of the modern ICU. In addition to this well-cited contribution to modern critical care, the Johns Hopkins neurosurgeon, Walter Dandy, created an earlier version of the modern ICU in 1923, when he opened a three-bed unit for postoperative neurosurgery patients.[4] Max Harry Weil, another key figure in modern critical care, opened a four-bed "shock unit" in 1958 at the Los Angeles County + University of Southern California (LA+USC) Medical Center.[3]

Since the early ICUs, modern critical care has focused on continuous physiologic monitoring and the application of advanced life-sustaining therapies, including mechanical ventilation, extracorporeal membrane oxygenation (ECMO), and continuous renal replacement therapy. One astute observer and practitioner notes that the focus has often been on syndromes—sepsis, acute respiratory distress syndrome (ARDS), acute renal failure, and delirium—rather than specific diseases.[4] The progress in care for these syndromes and other critical care challenges has often been exciting but has also required periodic major shifts in practice, most notably with regard to sedation, mechanical ventilation in ARDS, use of the pulmonary artery catheter (PAC), intensive insulin therapy, and perhaps also goal-directed therapy.

Anesthesiologists, dating back to Dr. Ibsen, have been central to the development of modern critical care, both with the advancement of clinical practice and the development of technology and tools essential to the practice of the specialty. George Gregory, a pediatric anesthesiologist and intensivist at the University of California, San Francisco (UCSF), and colleagues used continuous positive airway pressure (CPAP) in the treatment of neonatal idiopathic respiratory distress syndrome and demonstrated a dramatic improvement in survival.[5] John Severinghaus, who was not an intensivist but certainly a major figure in the field of anesthesiology, was the key contributor to the development of the first blood gas electrode apparatus in the late 1950s.[6] More recently, however, there appears to be a decline in the role of the critical care anesthesiologists in the United States. In 2001, several academic leaders from the United States and Europe authored an editorial raising alarm based on the following: less than 4% of U.S. anesthesiologists have a special certificate in critical care, only 12% of the members of the Society of Critical Care Medicine (SCCM) are anesthesiologists, and relatively few anesthesia critical care diplomates graduate each year from fellowships.[7] By contrast, in Europe, anesthesia intensivists continued to maintain a central role in the field of critical care medicine. In the nearly two decades since this article, it is unclear if much has changed. The number of accredited fellowship programs in anesthesia critical care has declined,[8] and the number of anesthesia critical care diplomates certified by the American Board of Anesthesiology remains low in comparison to other anesthesia subspecialties like pain medicine and pediatric anesthesiology.[9] It is unclear why critical care is a less desirable career path but key factors likely include limited exposure to high quality critical care rotations, lack of faculty mentors, and more favorable financial incentives in anesthesia-based fields. Despite these challenges, the Society of Critical Care Anesthesiologists continues to play a primary advocacy, educational, and mentoring role and memberships have increased over the past several years.[10]

The future roles of anesthesia intensivists in the United States are likely to expand due to the increasing complexity of perioperative medicine, coupled with an aging population in need for critical care. It is also interesting to note a recent proposal by several academic anesthesia leaders from both trauma and critical care of a new paradigm: acute care anesthesiology.[8] Modeled in part on acute care surgery, this new pathway and fellowship would include training in prehospital and emergency care, trauma, and critical care. Specifics of such a training pathway remain unclear but there are compelling reasons to consider this approach as another means of enhancing the anesthesiologist's role in resuscitation and emergency care.[11,12]

Intensive Care Unit Structure and Management

CAPACITY, UTILIZATION, AND COST

ICU bed utilization and cost vary considerably among developed countries. Recognizing that the definition of an ICU bed also varies considerably, the United States, Belgium, and Germany having greater than 20 ICU beds per 100,000 population whereas the United Kingdom, the Netherlands, France, and Spain have fewer than 10 ICU beds per 100,000 population.[13] Similarly, there are also large variations in the volume and type of ICU admissions in developed countries.[14] Part of this can be attributed to differences in bed availability, but it also reflects different approaches to admission and triage that have been well described.[15-17] A recent large prospective study of noncardiac surgery in Europe demonstrated high mortality rates and significant variability in utilization of critical cares services.[18] Perhaps most striking was the finding that among surgical patients who died, the overwhelming majority (73%) were never admitted to an ICU. Therefore, despite concerns about over-utilization of expensive resources in some countries, this study suggests an alarming under-utilization of essential critical care services.

In the United States, in particular, there is continued growth in ICU beds and cost, whereas occupancy has remained generally flat. In 2005, there were 93,955 ICU beds with occupancy rates of 68%. Critical care costs represented 13.4% of all hospital costs and 0.66% of gross domestic product.[19] By 2010, critical care beds had increased to 103,900 with stable occupancy rates over the previous decade. The greatest growth occurred in neonatal ICU beds with similar, but much lower, growth rates in adult and pediatric ICU beds. Critical care costs also grew to $108 billion, which represented an increase relative to gross domestic product (now 0.72%).[20] The type of growth in ICU beds is also worth noting, as described in a recent analysis of Medicare and Medicaid data.[21] Over 15 years, more than 72% of total ICU bed growth occurred in teaching hospitals. Multivariate analysis also demonstrated that large hospitals with high occupancy and teaching hospitals with high occupancy were most associated with next-year growth in the number of ICU beds. The investigators concluded that this may represent a type of "de facto regionalization," which may in turn lead to higher quality of care. What is more, they suggest their results also contradict the theory that ICU bed growth and supply represents a type of "demand elasticity,"[22] whereby increasing supply drives demand without clear benefits to patient care and the potential to change practice patterns and increase costs.[23,24]

STRUCTURE AND STAFFING PATTERNS IN THE INTENSIVE CARE UNIT

Much like the number and use of ICU beds, there is considerable variability throughout the world in the structure and staffing of ICUs. North American ICUs, when compared to the rest of the world, are more likely to have an "open" structure and be stratified into medical and surgical units and are less likely to have 24/7 intensivist presence.[25] ICUs are sometimes described as "open" or "closed;" however, a common research approach is to categorize staffing as "low intensity" (no intensivist or only elective intensivist consult) or "high intensity" (all care directed by intensivist or mandatory intensivist consult).[26] Much attention over the past two decades has focused on the optimal ICU structure and staffing models: specialized versus mixed, "high intensity" versus "low intensity," optimal physician and nursing staffing ratios, nighttime intensivist staffing, use of advanced practice providers (APPs), and best ICU team structure.

The data do not demonstrate a clear outcomes benefit to specialized units but do show increased mortality for patients "boarding" on a non-primary unit in a specialized system.[27] Many studies, including two large systematic reviews, have investigated outcomes associated with the intensity of ICU staffing.[26,28-34] The outcomes have been mixed but generally favor improved mortality and length of stay outcomes with a "high-intensity" model. Data are more limited with regard to provider-to-patient ratios, but a recent retrospective study in the United Kingdom did show a U-shaped relationship between patient-to-intensivist ratios, with an optimal ratio of 7.5. Optimal nursing ratios are also not well described but a large, multinational observational study demonstrated that nurse-to-patient ratios higher than 1.5 are associated with lower risk of in-hospital death.[25] The Working Group on Quality Improvement of the European Society of Intensive Care Medicine (ESICM) recommends 8 to 12 beds as optimal size.[35]

The use of nighttime intensivists is an active area of study, with most studies demonstrating a lack of mortality benefit.[36-39] It is important to note, however, that there is evidence that nighttime intensivist staffing, in one study, was associated with reduced in-hospital mortality in ICUs with low-intensity daytime staffing.[39] Furthermore, a before-and-after prospective study of 24/7 mandatory intensivist presence showed an association with reduced hospital length of stay and complication rate, as well as improved staff satisfaction and adherence to processes of care.[40] Based on available data, some investigators and critical care organizations (CCOs) have concluded that nighttime intensivists are costly and without significant benefit,[36,41] whereas others vigorously argue for the value of a 24/7 intensivist model in high complexity, high-volume ICUs, emphasizing that the benefits derive not just from intensivist presence but rather intensivist-led changes in the systematic delivery of care.[42]

Much attention has focused on the best approach to team structure and function in the ICU. As discussed earlier, "open" or "low-intensity" ICUs use hospitalists or emergency medicine physicians to care for patients in the ICU. Many academic and community-based institutions use nurse practitioners (NPs) and physician assistants (PA)—often described as advanced practice providers (APPs)—as core members of the team, largely because of the limited availability of intensivists.[43] Studies demonstrate equivalent mortality and length of stay outcomes when compared to teams that include both residents[44] and pulmonary/critical care fellows.[45] A larger, more recent retrospective study of cohort data from 29 ICUs in 22 hospitals examined the association between exposure to NP/PA ICU staffing and in-hospital mortality. While the patients in NP/PA-staffed ICUs had lower severity of illness and use of mechanical ventilation, the unadjusted and risk-adjusted mortality was similar in ICUs with and without NPs/PAs.[46] In addition to these outcomes, there is evidence of positive perceptions of NPs/PAs from other ICU providers, including physicians, nurses, and respiratory therapists.[47] Accessibility, communications skills, and knowledge of and adherence to guidelines were recognized as core strengths of the NPs and PAs.

In addition to the benefits of nonphysician providers, there is evidence supporting the benefits of multidisciplinary teams and interprofessional practice in the care of critically ill patients. A retrospective study of medical ICU patients in Pennsylvania hospitals demonstrated the greatest mortality benefit to high-intensity intensivist staffing and daily multidisciplinary rounds.[48] A recent review of interprofessional practice describes the robust literature supporting the value of interprofessional practice in the ICU.[49] Pharmacists, respiratory therapists, and physical and occupational therapists are essential providers in the daily care of critically ill patients and improve short-term and longer-term outcomes.

There are guidelines and expectations that address some of the previously discussed aspects of ICU structure. The Leapfrog Group, a major nonprofit "watchdog" organization, rates hospitals on many factors including ICU staffing. The highest Leapfrog rating with regard to the ICU requires all critical care patients to be managed or actively comanaged by a board certified intensivist.[50] The SCCM's Task Force on Models of Critical Care concludes that an "intensivist-led, high-intensity" team is an "integral" part of care delivery in the ICU. These guidelines do not make a recommendation for either direct management of all patients (i.e., "closed" model) or mandatory consultation by an intensivist.[51] Similarly, the SCCM's Admission, Discharge, and Triage Task Force makes a 1B recommendation for a high-intensity staffing model with "day-to-day" management either via a fully "closed" structure or with a mandatory intensivist model; the SCCM does not recommend 24-hour intensivist staffing *if* the ICU operates within a high-intensity structure.[52]

MANAGEMENT AND QUALITY IMPROVEMENT

The quality of an ICU depends to a significant degree on the management structure, as well as the organizational approach to clinical practice and process, and quality improvement. Management structures vary but have typically included at least a medical director and head nurse or nurse manager as a basic leadership structure.[35] Experts and critical care societies recognize the challenges and importance of selecting and developing skilled critical care leaders. One recent review highlights the need for a leader to maintain and foster "continuity, consistency, and communication" in both clinical practice and the organizational practice.[53] Although this may seem straightforward, the critical care leader often operates in a demanding and complex environment and must have a strong understanding of the broader health system operations and finances. Equally important are strong leadership skills, especially the ability to listen and learn, adapt to changing clinical and organizational circumstances, and constantly serve as a "catalyst for change."[54]

Beyond development of individual leaders, organizations are increasingly focused on how to best integrate ICUs and their leaders within a critical care structure. The SCCM's Academic Leaders in Critical Care Medicine Task Force highlights the growing number of academic medical centers now with CCOs. They describe a road map for integration of operations to focus on patient quality, safety, and value: first using a "horizontal" approach with all ICUs operating in a single system with defined responsibility and accountability for value-based care; and then a "vertical" approach using a population health model with care provided across the continuum for all critically ill patients during and after ICU care.[55] The Task Force also presents a follow-up plan for integration of critical care services into a single organization that explicitly includes the academic missions of research, professional development, and education.[56]

High quality clinical practice and appropriate use of expensive and oftentimes limited resources benefit from a clear set of administrative and clinical guidelines. The SCCM recently revised the Admission, Discharge, and Triage Guidelines, which provide useful guidance for institutions developing policies and protocols for patient flow and quality assurance.[52] Experts and professional societies agree that specific protocols of care—applied to practices like central line insertion and management of mechanical ventilation, and broader challenges like the use of the ICU for potentially inappropriate care—can help provide high quality, high value care in a collaborative model.[57,58] Checklists and bundles often form the foundation for standardization of care and function as a mechanism to implement evidence-based practices and guidelines. The SCCM's ICU Liberation project, for example, provides the ABCDEF Bundle as a daily, standardized approach to the implementation of the guidelines for the Prevention and Management of Pain, Agitation/Sedation, Delirium, Immobility, and Sleep Disruption in adult ICU patients.[59,60] Standardization of care is a necessary step, but quality and value also depend on a robust approach to process improvement. Each ICU or CCO must first define the quality and safety metrics to be measured.[61] It is also important that ICUs and CCOs consider the entire scope of quality in critical care. Recent guidelines describing best practices for family-centered care in the ICU highlight the importance of including measures of family support in our definition of quality in critical care.[62] Once defined, the organization's quality efforts will largely be determined by its ability to collect, analyze, and disseminate data to key leaders and ICU providers and staff.[51,63]

In summary, critical care is a relatively young medical specialty with a strong history of anesthesiologist involvement since its inception. The practice of critical care medicine continues to grow and evolve rapidly, in terms of medical advancement, practice structure, and integration into the broader landscape of population health. In the next sections we will discuss several of the central disease syndromes and therapeutic modalities that have come to define the modern practice of critical care medicine.

Acute Respiratory Distress Syndrome and Lung Protective Ventilation

ACUTE RESPIRATORY DISTRESS SYNDROME

ARDS is a final common state in acute lung injury characterized by noncardiogenic pulmonary edema, heterogeneous consolidation, decreased lung compliance, and severe hypoxemia. It is a syndrome that involves injury and increased epithelial-endothelial permeability of the alveoli. It can occur as a result of direct chemical injury, systemic inflammation including sepsis, trauma, or numerous other causes common in critically ill patients.

The 2012 Berlin definition of ARDS focused on clarifying the quantification of hypoxia, the acute timing, and the radiographic findings. Using the ratio of arterial oxygen tension to fractional inspired oxygen (PaO_2/FiO_2), ARDS is graded mild if this ratio is 300 mm Hg or less, but greater than 200 mm Hg; moderate if 200 mm Hg or less, but greater than 100 mm Hg; and severe if 100 mm Hg or less. These measurements should be obtained with a positive end expiratory pressure (PEEP) of at least 5 cm H_2O. The onset must be within 7 days of the presumed inciting insult, and bilateral lung infiltrates must not be fully explainable by other causes including cardiogenic pulmonary edema, effusions, or lobar collapse (Table 83.1).[64]

"BABY LUNG"

Imaging studies have shown that ARDS involves heterogeneous lung consolidation and small regions of remaining aerated lung. As a result, the entire mechanical stress of ventilation is borne by the small remaining regions of aerated lung. This concept has been described as the "baby lung" by some authors, and ventilation strategies have focused on preventing mechanical trauma and optimizing aeration of the remaining functional "baby lung."[65]

LUNG PROTECTIVE VENTILATION

The modern approach to mechanical ventilation in critically ill patients has been characterized by a focus on the prevention of ventilator-induced lung injury. In their landmark ARMA study of tidal volume, the ARDS Network group demonstrated significant decrease in mortality and

TABLE 83.1 Categorization of ARDS Severity With At Least 5 cm H_2O of PEEP

ARDS Severity	PaO_2/FiO_2
Mild	300-200 mm Hg
Moderate	200-100 mm Hg
Severe	100 or less mm Hg

Berlin definition of ARDS also includes: Time course within 1 week of inciting event. Bilateral infiltrates not otherwise explained. Fluid overload and cardiogenic edema excluded as primary causes.[64]

ARDS, Acute respiratory distress syndrome; *PaO_2/FiO_2*, ratio of arterial oxygen tension to fractional inspired oxygen; *PEEP*, positive end-expiratory pressure.

ventilator days with the use of lung protective ventilation, 6 mL/kg of predicted body weight (PBW) with plateau pressures less than 30 cm H_2O compared to ventilation at 12 mL/kg of PBW.[66] This lung protective, low-tidal-volume ventilation strategy has become standard of care for patients with ARDS and subsequent studies have associated improved outcomes even in patients without ARDS.[67-70]

PERMISSIVE HYPERCAPNIA

During low-tidal volume ventilation, hypercapnia often occurs. While the avoidance of ventilator-induced lung injury is beneficial, the exact degree and pleomorphic effects of hypercapnia are less clear.[71] There have been mixed data on the effects of hypercapnia on pulmonary inflammation, cellular and immunologic function, and wound healing.[72-74] Furthermore, hypercapnia may impair right ventricular function, exacerbate pulmonary hypertension, and predispose to cardiac arrhythmias.[75] As a result, most critical care practitioners adopt a pragmatic approach specific to the patients—often described as "permissive hypercapnia"—targeting a pH greater than 7.25. Extracorporeal carbon dioxide removal devices have been in active development to facilitate the management of carbon dioxide clearance during lung injury and low-tidal volume ventilation.[76] However, these invasive devices have yet to prove their clinical utility and effectiveness.[77]

VENTILATION MODES IN ACUTE RESPIRATORY DISTRESS SYNDROME

In the era of lung-protective ventilation, ventilation strategies have focused on preventing volutrauma, barotrauma, and atelectrauma. Volutrauma is injury to alveoli from excessive volume distention and is closely related to barotrauma from excessive force on the alveolar walls. Atelectrauma is related to the repeated collapse and reopening of alveoli.[78]

Conventional modes of ventilation deliver controlled pressure or flow profiles to the airways at tidal volumes larger than dead space and at rates similar to natural respiration. Gas transport occurs due to cyclic bulk flow into and out of the alveoli. Between the traditional ventilation modes of pressure control and volume control, there has been no significant difference shown in ARDS as long as low tidal volumes are used.[79]

Airway pressure release ventilation (APRV) is a mode of ventilation that holds a high constant inspiratory pressure with periodic brief releases to a lower pressure, with spontaneous respiratory activity superimposed on this pattern. The proposed benefits are increased aeration and reduced cycling of alveolar collapse.[80] A review of observational studies in trauma patients has suggested that early use of APRV may reduce the incidence of ARDS; however, more rigorous studies will be needed to evaluate this hypothesis.[81] Given the risks and unproven clinical benefits of this ventilator mode, its use remains controversial.[82,83]

High-frequency oscillatory ventilation (HFOV) is another less conventional mode of ventilation that requires a special oscillator pump. HFOV delivers very low volumes, often less than 100 mL, at very high rates, typically hundreds of breaths per minute. In HFOV, because tidal volumes are less than dead space, gas transfer does not depend on bulk flow but on other mechanisms, such as "pendelluft" (swinging air) effect and enhanced diffusion. Whereas initial studies demonstrated improved oxygenation, a subsequent larger clinical trial demonstrated no benefit or increased mortality in patients with ARDS.[84,85] As a result, HFOV is not recommended, except as a rescue method in refractory hypoxia.[86]

POSITIVE END-EXPIRATORY PRESSURE AND OPEN LUNG STRATEGIES

ARDS is characterized by extensive alveolar collapse. Repeated opening and closing of alveoli during ventilation results in atelectrauma to the lungs. The lung compliance curve is characterized by hysteresis, meaning a higher driving pressure is required to inflate the lungs during inspiration, as compared to lower driving pressure required to keep the lung open during expiration. As a result, the use of PEEP and more generally "open lung" strategies have received significant attention.

POSITIVE END-EXPIRATORY PRESSURE

PEEP is a continuous pressure held in the airways even on expiration. Increasing PEEP improves oxygenation by increasing functional residual capacity and preventing alveolar collapse on expiration, thus maintaining alveolar recruitment. Excessive PEEP can result in regional or global lung over-distention or exacerbate air trapping. Furthermore, excessive PEEP impairs right ventricular function and venous return, possibly necessitating excess intravenous fluid administration.

Early animal studies demonstrated that the use of PEEP ameliorates ventilation-induced lung injury.[87] As such, a minimum of 5 cm H_2O of PEEP is recommended by ARDS net ventilation protocol.[66] However, large clinical studies comparing lower PEEP protocols to higher PEEP protocols failed to demonstrate improvement in clinical outcomes, although oxygenation was improved.[88-90] The failure of these studies led to the more sophisticated methods of titrating PEEP usually included in open lung strategies (OLSs).

OPEN LUNG STRATEGIES

OLS are the combination of lung protective ventilation with PEEP optimization and possibly recruitment maneuvers. The goal is to maintain aeration of functional lung tissue, thereby preventing atelectrauma, cyclic collapse of the alveoli, and focal lung stress in the remaining compliant regions of the lung. Various PEEP titration strategies have been integrated with recruitment maneuvers into "open lung" strategies.

Esophageal Manometry, Transpulmonary Pressures, and Positive End-Expiratory Pressure

One proposed method is using esophageal pressures to guide determination of the best PEEP. The mechanical stresses of airway pressure can be separated into two components borne by the intrinsic lung compliance and the external chest wall compliance. However, only the lung component, as quantified by the transpulmonary pressure, is involved in ventilation-associated lung injury.[91] The relative contributions of these two components can be difficult to predict and are affected by numerous conditions including ARDS, pulmonary edema, atelectasis, obesity, abdominal compartment syndrome, and burns.[92,93]

The transpulmonary pressure is calculated by subtracting the pleural pressure, outside the lung but inside the chest wall, from the total airway pressure. Pressure measurements in the esophagus are considered a surrogate of pleural pressure. This can be performed by placing a specifically designed air-filled pressure transducing catheter, similar to an orogastric tube, in the esophagus.[91] With this method, PEEP can be titrated to prevent negative transpulmonary pressures that collapse the lung at the end of expiration. This holds special promise for patients with abnormal chest wall compliance, such as those with morbid obesity.

Titration of PEEP using esophageal pressures in ARDS may allow the use of higher airway pressures without risking lung injury.[94] One clinical study demonstrated improved oxygenation and lung compliance with this approach in association with higher PEEP, but further studies will need to be performed to prove improvement in outcomes of this approach.[95]

Decremental Positive End-Expiratory Pressure Trials

Trials of decremental PEEP have involved raising PEEP to a high level (20-25 cm H_2O) after a recruitment maneuver. The PEEP was then slowly decreased in a stepwise manner. The final PEEP was set at the level that maximized lung compliance, driving pressure divided by tidal volume.[96] Initial clinical results of OLSs demonstrated promising physiologic improvement in patients with severe ARDS. However, these initial studies were heterogeneous in nature, and in the largest randomized prospective trial of an open lung protocol, 6-month mortality, ventilator days, and risk of pneumothorax was actually increased.[97-100] Criticisms of this latter study include use of high recruitment pressures resulting in increased barotrauma and hemodynamic instability. Further research will need to be performed to elucidate the best recruitment and PEEP strategies in ARDS.

Recruitment Maneuvers

The goal of recruitment maneuvers is to aerate previously collapsed lung, thereby improving gas exchange and overall lung stress. The most common recruitment maneuver is simply holding sustained airway pressure for a set time period, typically 30 to 40 cm H_2O for 30 to 40 seconds. This therapy is not benign, and common complications include transient hemodynamic instability, oxygen desaturation, ventilator dyssynchrony, or rarely pneumothorax.[101] As such, the patient should be closely monitored during and after recruitment manuvers. Another potentially gentler method of recruitment is incremental PEEP titration. PEEP is increased in a stepwise manner of 2 to 5 cm H_2O every 3 to 5 minutes until there is a worsening of respiratory or hemodynamic parameters. However, there is little evidence of the superiority of any specific recruitment maneuvers. Furthermore, there is an overall lack of strong evidence for improved clinical outcome; thus, the role of recruitment maneuvers in ventilation strategies is uncertain.[99]

PRONE POSITIONING

Prone positioning has a number of physiologic benefits in ARDS. Ventilation-perfusion matching and lung aeration is improved, and parenchymal heterogeneity is reduced. This likely contributes to a protective effect against ventilator-induced lung injury.[102] In the largest study of only patients with severe ARDS, defined as PaO_2:FiO_2 less than 150 mm Hg, 28-day mortality was significantly reduced.[103] As such, prone positioning is recommended in severe ARDS, with the caveat that benefits were demonstrated at centers with deep experience. At centers with less experienced practitioners, prone positioning may be technically challenging with risk for increased serious complications.[104]

SELF-INDUCED LUNG INJURY

In negative pressure spontaneous respiration, the chest wall exerts a negative pressure on the lungs. In instances of increased respiratory drive and lung injury, this can induce lung injury without positive pressure ventilation. In animal studies, chemically induced hyperventilation alone has been demonstrated to induce lung injury.[105] In mild lung injury, spontaneous respiration is associated with better oxygenation, improved dependent lung aeration, and decreased diaphragm atrophy. However, in severe lung injury, spontaneous respiration can be associated with increased lung injury.[106]

NEUROMUSCULAR BLOCKADE

Neuromuscular blocking agents have been used to facilitate synchrony with mechanical ventilation by removing spontaneous chest wall and diaphragm motion. This lowers ventilation pressures, decreases risk of barotrauma, and improves oxygenation. Additionally, some animal data suggest the neuromuscular blocking agent, cisatracurium, has direct lung-protective properties through antiinflammatory actions.[107] One observational study comparing vecuronium and cisatracurium found significantly fewer days on the ventilator with cisatracurium, although no difference in mortality or other clinical outcomes.[108] In a prospective study of neuromuscular blockade in ARDS, the ACURASYS study, cisatracurium administration for the first 48 hours was found to decrease lung injury and mortality in patients with severe ARDS whose PaO_2/FiO_2 was less than 150 mm Hg. Additionally, no increased incidence of weakness or critical illness myopathy was seen with this short duration of use.[109] However, this study was criticized for being relatively small, single centered, and for having insufficiently long follow up to evaluate critical illness myopathy. To address these concerns, the larger, multicentered Reevaluation Of Systemic Early Neuromuscular Blockade (ROSE) study was performed by the Prevention and Early Treatment of Acute Lung injury (PETAL) Network investigators.[110] In this more recent trial, early continuous neuromuscular blockade did not lower all-cause mortality at 90-days. There were no consistent between-group differences in outcomes at 3, 6, and 12 months. However, when compared to the ACURASYS trial, patients in the ROSE trial received higher levels of PEEP, and those not paralyzed also received lighter sedation, potentially contributing to the difference in observed outcomes. [110]

NONINVASIVE POSITIVE-PRESSURE VENTILATION AND HIGH-FLOW NASAL CANNULA

CPAP and bilevel positive airway pressure (Bilevel PAP) masks have been shown to be effective first-line treatment in respiratory failure due to acute cardiogenic pulmonary edema and chronic obstructive pulmonary disease (COPD).[111-113] However, their use in ARDS is controversial. Although avoidance of endotracheal intubation could have many benefits, studies have failed to show benefit in the need for intubation or mortality. In fact, in one study, noninvasive positive-pressure ventilation (NPPV) was associated with increased mortality compared to high-flow nasal cannula (HFNC).[114] Patients better tolerate HFNC than mask NPPV, and HFNC was not found to be inferior in intubation rates or mortality compared to NPPV.[115] However, the HIGH trial, a prospective, multicenter, randomized study in immunocompromised patients, failed to show any benefit in mortality, intubation rates, or even patient comfort.[116] Further research in the role of HFNC and other nonmask forms of NPPV is needed.

SUMMARY OF EVIDENCE-BASED VENTILATION IN ARDS AND FUTURE RESEARCH

The use of lung protective ventilation with 6 mL/kg of PDW is highly recommended. The use of PEEP at a minimum of 5 cm H_2O and titration based upon the ARDSnet protocol is recommended, but the optimal PEEP level is unclear. In severe ARDS, the early use of prone positioning has been shown to improve mortality. HFOV is not recommended as a primary ventilation method. Future research will need to establish the role of recruitment maneuvers and optimal PEEP titration strategies. The role of noninvasive ventilation, neuromuscular blockade, and the risk of self-induced lung injury will also need to be clarified in the treatment of ARDS.

Ultra low-tidal volume ventilation, 4 mL/kg of PDW or less, continues to be investigated. The technology of artificial gas exchange devices, extracorporeal carbon dioxide exchangers, or venovenous ECMO support, continues to be advanced.[117] Finally, despite negative trials of aspirin, statins, and beta-agonists, new pharmacologic and biologic therapies including mesenchymal stem cell therapies continue to be investigated.[69,118]

MANAGEMENT OF PAIN AND AGITATION

Sedatives are some of the most commonly administered medications in the ICU. The purpose of sedatives is to manage agitation to ensure the safety of the patient and care providers, and to prevent dangerous events such as unintended extubation. The first step to effectively manage agitation is to identify and address underlying causes. Pain is a common cause of agitation in the critically ill and is often underappreciated.[119] Delirium is extremely common in the critically ill and is associated with adverse outcomes including increased length of stay and mortality.[120] Delirium can manifest as hypoactivity or with agitation. The first-line interventions should be nonpharmacologic.

When sedatives are needed, targeting light sedation is recommended.[121] The use of light sedation is not associated with increased posttraumatic stress disorder,[122] and may be associated with shorter ventilator time or even decreased mortality.[122] The use of daily sedation interruptions or nursing-driven protocols with standardized tools are both effective methods to achieve this goal.[121] Two well-validated scales for sedation assessment are the Richmond Agitation-Sedation Scale and the Sedation-Agitation Scale.[123,124] Some even propose protocols that try to completely avoid traditional sedatives and focus primarily on analgesia and control of agitated delirium with haloperidol.[125] Though this approach may be associated with shorter length of stay and mechanical ventilation, further study is needed to confirm this finding. Furthermore, there is a suggestion that benzodiazepines lead to increased hyperalgesia with administered opioids. This should be considered in patients who require opioids for pain.[126]

Choice of specific sedative agent is controversial. However, benzodiazepines, when compared to propofol or dexmedetomidine, may be associated with increased delirium and length of mechanical ventilation.[127-130] Propofol, with the benefits of short duration and rapid titration, is a very common choice, but may cause hypertriglyceridemia or, rarely, propofol infusion syndrome. Propofol infusion syndrome is a serious complication associated with high dose and prolonged infusion duration that presents with metabolic acidosis, electrocardiogram (ECG) and conduction abnormalities, and rhabdomyolysis.[131] Dexmedetomidine is increasingly being used in the ICU. Several studies have suggested that it is less deliriogenic than other sedatives, or may even have prophylactic benefits against delirium.[132,133]

Neuroleptic drugs such as haloperidol are rarely used as primary sedatives, but can be used to control agitated delirium that may result in harm to patient or staff. However, studies have not shown clear benefit with the use of antipsychotics in the prevention or treatment of delirium.[134] Furthermore, many patients who start treatment with antipsychotics in the ICU are discharged with a prescription for antipsychotics with the accompanying dangerous side effects associated with long-term use.[135]

Pragmatically, regardless of the specific sedative agent or protocol and scales used, the evidence points toward using a systematic and adaptive practice of minimizing psychoactive agents, while maintaining safety of the patient and care providers.

Sepsis and Shock

INFECTION, SYSTEMIC INFLAMMATORY RESPONSE SYNDROME, AND SEPSIS

Sepsis is one of the most common diagnoses treated in ICUs. It is estimated that at least 1.7 million patients develop sepsis every year in the United States alone, the majority of whom are over the age of 65.[136,137] Mortality, which reaches 10% in patients with sepsis and 40% in patients with septic shock, is typically a result of multiple organ dysfunction synrome (MODS). Sepsis has been defined as a “life-threatening organ dysfunction that is a result of dysregulated host response to infection.”[138]

The most recent definition of sepsis (“Sepsis-3”), introduced in 2016 by the SCCM/ESICM task force, emphasizes the importance of organ dysfunction for sepsis diagnosis, as opposed to systemic inflammatory response syndrome (SIRS). Although features of SIRS (tachycardia, tachypnea, fever/hypothermia, leukocytosis/leukopenia) are found in many patients with sepsis, SIRS is not a specific response to infection and can develop in many noninfectious conditions (major trauma, major surgery, burns, necrotizing pancreatitis).[139] All patients with sepsis, however, have clinical or laboratory evidence of acute organ dysfunction (e.g., hypotension, hypoxemia, altered mental status, oliguria).

The transition from infection to sepsis is believed to occur when the inflammatory response to the pathogen becomes dysregulated, spreading beyond the original site of infection and leading to systemic organ dysfunction. The organ dysfunction has been defined as an increase in the Sequential Organ Failure Assessment (SOFA) score by at least 2 points. The SOFA score uses a simple numeric assessment (0-4) of neurologic, cardiovascular, respiratory, renal, liver, and hematologic function to assess the severity of a patient's physiologic deterioration (Table 83.2). While SOFA score per se is not diagnostic of sepsis, the increase in SOFA score in a patient with a suspected or confirmed infection indicates a substantially increased risk of in-hospital mortality. Clinicians must maintain a high suspicion for infection in all patients that manifest worsening organ function. It is important to note, however, that in approximately half of the cases of sepsis, the causative microbe is never identified.[138,140] This is because of the limitations of currently used culture-based microbiology methods, inadequate sampling, or concurrent treatment with antimicrobials. Because the initial clinical presentation of sepsis is variable and laboratory findings are nonspecific, detecting sepsis early remains a clinical challenge.

SEPTIC SHOCK

In patients with septic shock, the dysregulated host response to infection is associated with severe circulatory, cellular, and metabolic abnormalities. Required for the clinical diagnosis of septic shock is elevation of plasma lactate levels greater than 2 mmol/L and the requirement for vasopressor support to maintain mean arterial pressure (MAP) greater than 65 mm Hg despite adequate fluid resuscitation. Circulatory failure that occurs in septic shock is a result of vasodilation and increased vascular permeability, which lead to decreased effective circulating volume. Myocardial dysfunction develops in a significant percentage of patients with septic shock. Tissue perfusion is further impaired by tissue edema and aberrant activation of coagulation at the microvascular level. The ability of tissues to extract and utilize oxygen is also impaired, likely due to sepsis-induced mitochondrial dysfunction.[141] Reflecting these perfusion and cellular abnormalities are supranormal values of oxyhemoglobin saturation in mixed venous or central venous blood often found in patients with septic shock.

SURVIVING SEPSIS CAMPAIGN

The high prevalence, high mortality, and mounting costs of intensive care have led to continuous worldwide efforts to identify the best practices in sepsis, resulting in the Surviving Sepsis Campaign. These recommendations were published first in 2004 and revised in several subsequent editions. They emphasized sepsis as a medical emergency and advocated for management to be initiated immediately upon recognition.

It is broadly accepted that an early administration of appropriate antibiotic therapy, within 1 hour of sepsis recognition, is a key intervention to decrease patient mortality. Additional source control (i.e., drainage of an abscess or resection of infected tissues) may be critical in situations in which antibiotic therapy alone would not be curative (e.g., necrotizing soft-tissue infection).

The remaining recommendations for the management of sepsis and septic shock focus on physiologic stabilization (restoration of perfusion, adequate pulmonary gas exchange while avoiding ventilator-induced lung injury, correction of electrolyte abnormalities, and more). Administration of intravenous fluids (30 mL/kg or individualized) is recommended in all infected patients who demonstrate clinical or laboratory signs suggestive of impaired tissue perfusion (i.e., hypotension or lactate elevation greater than

TABLE 83.2 Sequential Organ Failure Assessment Score

	Score				
System	**0**	**1**	**2**	**3**	**4**
Central nervous system Glasgow coma scale	15	13-14	10-12	6-9	<6

MAP, Mean arterial pressure. Adapted from The Third International Consensus Definitions for Sepsis and Septic Shock (Sepsis-3).

4 mmol/L). Treatment with vasopressors is typically initiated when hemodynamic stability cannot be restored with fluid administration alone. To that end, norepinephrine is the recommended vasopressor of choice. Corticosteroids are helpful in decreasing vasopressor requirements and shock reversal but their impact on mortality is less clear.[142,143]

Despite the best available supportive care, shock develops in a subset of patients with sepsis that is refractory to treatment with antibiotics, fluids, vasopressors, and corticosteroids, and ultimately progresses to the failure of most organ systems. This is described as MODS. Encephalopathy, ARDS, liver failure, renal failure, and coagulopathy characterize this clinical picture that has an extremely high mortality.

HEMODYNAMIC SUPPORT IN SEPTIC SHOCK

Over the last 20 years, it has been intensely studied whether specific hemodynamic or metabolic indices should be uniformly achieved during resuscitation, with proponents of such an approach introducing the term "goal-directed therapy." Under such management, predefined "best" values of central venous pressure (CVP), MAP, central venous oxygen saturation ($ScvO_2$), or urine output would be achieved through administration of crystalloids, blood, vasopressors, and inotropes. While this protocolized approach was shown to decrease mortality in a single-center study by Rivers in 2001,[144] more recent multicenter clinical trials (ProCESS, ARISE, and ProMISe) have questioned the benefit of a stringent protocolized resuscitation.[145] Likely due to the improvements in general critical care over the last decade, these studies failed to demonstrate the survival benefit of protocolized hemodynamic resuscitation when compared to standard care. Hemodynamic resuscitation in shock is discussed in further detail in the following section.

Hemodynamic Resuscitation in Shock

Circulatory shock is a common condition in intensive care. It is defined by insufficient end-organ perfusion and, if left untreated, leads to end-organ dysfunction and failure. The purpose of fluid administration in circulatory shock is to increase cardiac output (CO) and thus increase end-organ perfusion. Traditional fluid resuscitation strategies were based on empiric intravenous fluid administration and static markers of cardiac preload such as CVP or pulmonary capillary wedge pressure.

In the landmark 2001 paper, Rivers and associates demonstrated a significant mortality decrease, 30.5% versus 46.5%, in patients with septic shock with the use of an early goal-directed therapy (EGDT) protocol versus standard care.[144] EGDT was an emergency department-based protocol that focused on meeting concrete targets of CVP, oxygen delivery, and $ScvO_2$. This involved aggressive fluid resuscitation, allogenic red blood cell transfusion, and inotropic support per algorithm. Subsequent studies called various parts of this aggressive protocol into question. Three larger, multicenter prospective randomized studies showed no difference between EGDT and standard care.[146,147] Thus, the benefit of the EGDT may have been due to the early intervention by a specialized treatment team, rather than the aggressive therapy protocol.[148]

This data emerged with increasing evidence of harm caused by excessive intravenous fluid administration. One multicentered retrospective study of patients in septic shock demonstrated an association between positive fluid balance, higher CVP, and mortality.[149] Another multicentered observational study associated positive fluid balance with increased mortality and renal failure.[150] In a prospective randomized trial, a conservative fluid protocol demonstrated significantly shorter ICU length of stay and fewer ventilator days in patients with ARDS, but no difference in mortality.[151] Data from the CLASSIC trial demonstrated feasibility of a fluid restrictive protocol in critically ill septic patients without apparent worsened outcomes, but it was underpowered for many important clinical outcomes.[152]

Although fluid resuscitation in septic shock is standard of care, there is no high-quality large-scale clinical outcomes data on the efficacy of intravenous fluid resuscitation. In the thought-provoking multicentered 2011 FEAST trial, children presenting with septic shock in a resource-poor setting were prospectively randomized to intravenous fluid administration.[153] Surprisingly, mortality was increased in the fluid administration arm, primarily from cardiovascular collapse.[154] In adults, a single center randomized study of patients with septic shock in a resource-limited setting also saw increased mortality when randomized to more aggressive intravenous fluid administration.[155] Given the specific resource-limited setting and patient population in these two studies, the results are not generalizable. However, these unexpected results do challenge the traditional dogma of intravenous fluid administration in septic shock[156] and raises questions about the Surviving Sepsis Campaign's recommendation for 30 mL/kg crystalloid bolus in the initial management of septic shock.

Modern fluid resuscitation strategies in circulatory shock are shifting away from empiric intravenous fluid volumes toward a rational approach of supporting perfusion pressure, identifying end-organ malperfusion, evaluating fluid responsiveness, and administration of fluids to augment CO in a targeted manner.

END-ORGAN PERFUSION

Since the goal of fluid resuscitation is to restore end-organ perfusion, the first step should be to identify end-organ malperfusion. There are many surrogates used as indicators for end-organ perfusions, but they all have their limitations and confounders. The most commonly used markers in shock are urine output, lactate, and base deficit.

Urine Output

Urine output is almost universally measured in critically ill patients. Urine output of less than 0.5 mL/kg/hour is a common cut-off used in adults as a marker for systemic malperfusion or hypovolemia. However, urine output is not directly correlated to end-organ perfusion and injury.[157] There are many confounders, especially in the critical care setting, including neurohumoral effects, diuretic use, intrinsic kidney injury, obstructive uropathies, and exogenous vasopressin administration. Despite these many limitations, the ubiquity of this measurement has made it a core component of evaluating a patient in shock.[158] There is further research examining real-time urine output rate as a more effective monitor in shock and may be associated with decreased rates of acute kidney injury.[159,160]

Lactate

Lactate is one of the most commonly measured markers of organ ischemia. Lactate is a product of glycolysis and even under normal physiologic conditions is produced at a high rate. Although production may be increased by tissue-level hypoxia, there are many other causes of increased lactate production that are not secondary to lack of perfusion. These include β-adrenergic activation, acute lung injury, or medications. Further, lactate clearance can be reduced by hepatic or mitochondrial dysfunction. Thus, although elevated lactate levels are associated with poor outcomes in shock states, it may not be a specific marker for organ malperfusion or ischemia.[161]

Standard Base Deficit

Standard base deficit is a calculated value based on blood gas measurement as a gauge of metabolic acidosis. It approximates the amount of base that must be added to in vitro blood at 37°C and P_{CO2} of 40 mm Hg to bring the pH to 7.4. Like lactate, elevated base deficit has been associated with mortality and poor clinical outcomes in shock states, especially in trauma. However, base deficit is affected by many factors. It can also be confounded by nonperfusion-related conditions including sodium and chloride concentrations, hypoalbuminemia, respiration, exogenous sodium bicarbonate, or sodium chloride administration.[162,163]

Other Tissue-Specific Perfusion Markers

The three traditional markers of end-organ perfusion discussed thus far are global markers that may be normal even when there is regional organ level malperfusion. Newer techniques, such as near-infrared spectroscopy, transcutaneous oximetry, and gastric pH/tonometry, may provide a more specific and sensitive endpoint target in shock.[164-167] Currently, however, these technologies are primarily used in research and there is no strong clinical evidence of superior clinical outcomes compared to traditional endpoints.[168] Future developments will also likely involve organ or inflammation-specific biomarkers.

CARDIAC OUTPUT

The purpose of intravenous fluids during resuscitation is to increase CO; therefore, it is important to evaluate the adequacy and the response of CO to avoid excess intravenous fluid administration. There have been an increasing number of noninvasive technologies available to measure CO in the ICU to supplement the physical examination. Each has its own strengths and weaknesses, but no single technology has been proven clinically superior. The absolute measurement accuracy of many of these devices is highly variable, especially under rapidly changing hemodynamic conditions. Although the different methods have been validated individually, actual interdevice agreement is likely poor.[169,170] Measurements from one device cannot be directly compared to another; this may be true even within the same technology from different manufacturers.[171] Several of the most commonly used CO measurement techniques are reviewed in the next section. Refer to Chapter 36 on cardiovascular monitoring.

Pulmonary Artery Catheter, Thermal Dilution

PACs are considered the gold standard of CO measurements. In addition to direct measurement of pulmonary artery and pulmonary capillary wedge pressures, it allows for thermal dilution measurements of CO. This method involves injecting a known amount of cold solution into the right atrium and measuring the temperature change over time in the pulmonary artery. Based on the Steward-Hamilton equation, the area under the curve of the temperature change is inversely proportional to the CO. Current PACs also offer continuous CO measurements with thermal heating elements proximal to the pulmonary artery. Although thermal dilution PAC is the gold standard, precision error is approximately 15% to 20% even in idealized laboratory conditions.[172,173] This precision is further worsened in patients with low CO or severe tricuspid regurgitation.[174] Although PACs were once widely used in critically ill patients, their routine use has fallen out of favor after multiple studies failed to demonstrate improved clinical outcomes and the possibility of increased complication rates with PAC usage.[174,175] In select patients, PAC still provides valuable information during shock resuscitation and can be used to monitor pulmonary artery pressures, CO, and CO responses to intravenous fluid challenges.

Transpulmonary Thermal Dilution or Lithium Dye Dilution

Transpulmonary thermal or other dye dilution techniques use the same principles of the Steward-Hamilton equation; however, the indicator solution is injected into the superior vena cava and the change is measured near the aorta, typically on a femoral or axillary arterial line. The advantage of this technique is that it does not require placement of a PAC and is easy to use. Accuracy and precision are similar to PAC measurements, although it also becomes inaccurate at low CO.[176,177] These systems also allow the measurement of other physiologic parameters such as extravascular lung water.

Pulse Contour Analysis

Pulse contour analysis measures CO by analyzing the morphology of the arterial pressure waveform and thus requires a good quality arterial line tracing.[178] By measuring the area under the systolic portion of the curve and estimating the arterial impedance, the stroke volume can be derived.[179] In modern systems, this is combined with proprietary algorithms with more advanced waveform analysis.[169] These methods suffer from drift and inaccuracy in rapidly changing hemodynamic states, so they are often coupled with thermal or dye dilution techniques for intermittent calibration.[171] The advantages of these devices are in providing a continuous measurement of stroke volume and stroke volume variability, while avoiding the need for central line. These devices have been investigated in perioperative hemodynamic optimization with mixed results in improving clinical outcomes.[180,181]

ELECTRICAL BIOREACTANCE AND IMPEDANCE

Bioreactance and bioimpedance methods measure CO by measuring the changing properties of an electric field placed across the thorax. This is related to the movement of blood into and out of the chest and thus the CO. The main advantage of this technique is that it is minimally invasive and only requires several electrodes placed on the chest. The accuracy of these devices can be variable depending on the clinical situation, and measurements may correlate poorly with other techniques.[182,183]

TRANSTHORACIC AND TRANSESOPHAGEAL ECHOCARDIOGRAPHY

Focused cardiac ultrasound and echocardiography can be used to measure stroke volume and stroke distance.[184] This is performed by pulse wave Doppler integration of systolic flow at the left ventricular outflow tract (LVOT). This is typically performed from the transthoracic apical window or the deep transgastric esophageal window. The volume-time integral (VTI) of the flow velocity curve gives the stroke distance. The VTI multiplied by the LVOT cross-sectional area gives the stroke volume, but VTI alone can be used as an index of stroke volume. However, this technique is very operator dependent, can be labor intensive, and does not account for aortic valve regurgitation. Furthermore, some studies have reported poor agreement with other methods of CO measurement.[185]

Esophageal Doppler operates in a similar manner, except the probe is placed in the esophagus and measures velocities in the descending aorta. These velocities are then indexed to the patient to estimate the total CO.[170,186]

Mixed Venous and Central Venous Saturation

Mixed venous oxygen saturation drawn from the pulmonary artery is a powerful indicator of the balance between global oxygen delivery and global oxygen consumption. Although CO can be calculated using Fick's principle with assumptions about oxygen consumption, a low mixed venous oxygen saturation, less than 65% to 70%, indicates a deficit of oxygen delivery relative to oxygen consumption. Since it is a global measure, organ-specific ischemia may be present even with normal or elevated mixed venous saturations.[187]

Measurement of mixed venous oxygen saturations requires placement of a PAC. As a result, some have proposed central venous saturation from the vena cava as a surrogate. Unfortunately, the relationship between central venous saturation and mixed venous saturation has been found to be variable.[188,189]

FLUID RESPONSIVENESS

The hemodynamic purpose of intravenous fluid administration is to increase global oxygen delivery by increasing CO. In this regard, the administration of intravenous fluid is only beneficial if it increases CO. A patient is considered "fluid responsive" if they are able to increase their CO to a fluid bolus.

Traditional static indicators for fluid administration were measurements of filling pressures to the left or right ventricle. These included CVP[190] and pulmonary capillary wedge pressures. These measurements also have their ultrasound corollaries: inferior vena cava diameter, end diastolic, and end-systolic ventricular diameter. Unfortunately, despite their widespread use, these static indicators of preload, and even their trend, have been found to be poor predictors of volume responsiveness.[191]

As a result, dynamic indicators of fluid responsiveness have become increasingly used. The most straightforward dynamic test of fluid responsiveness is a fluid challenge with measurement of CO before and after. Typically, a small bolus of approximately 100 to 250 mL of intravenous fluid is used. Similarly, a passive leg raise test resulting in transient autotransfusions from the lower extremities has also been shown to be an effective predictor of fluid responsiveness.[192]

Other dynamic indicators depend upon cardiopulmonary interactions and the consistent variations of intrathoracic pressure created by controlled mechanical ventilation to create detectable beat-to-beat variations in stroke volumes. As positive pressure breath is delivered, right ventricular preload is decreased and afterload increased. Meanwhile, the left ventricle preload experiences a transient increase and then a decrease as left ventricular afterload increases. This process is reversed on expiration.[193] If the stroke volume is sensitive to these swings in preload, the stroke volume will vary significantly during the respiratory cycle and is indicative that the patient is likely volume responsive.[191,194,195] The measured parameters can be stroke volume variation, pulse pressure variation, or inferior vena cava distensibility[196,197] on ultrasound; various studies have reported different cut-offs for predicting volume responsiveness. These techniques may not be accurate in arrhythmias, right or left heart failure, or low-tidal volume ventilation.[193] However, these dynamic indicators have been shown consistently superior in predicting volume responsiveness compared to static preload measures.

SUMMARY OF FLUID RESUSCITATION IN SHOCK

The goal of intravenous fluid administration in shock is to restore end-organ perfusion by augmenting CO. There is increasing evidence that excess intravenous fluid administration is harmful in critically ill patients. Thus, the patient should be assessed for end-organ malperfusion, insufficient CO, and likelihood of fluid responsiveness prior to and during fluid resuscitation.[198,199]

Care for Patients Receiving Cancer Immunotherapy in the Intensive Care Unit

Cancer immunotherapy is a rapidly evolving field of oncology. Two major therapeutic approaches utilized in cancer immunotherapy are based on either enhancing the patient's own antitumor immunity (immune checkpoint inhibitors, cytokines, vaccines) or administration of tumor-reactive immune cells (chimeric antigen receptor [CAR] T cells, T-cell receptor engineered T cells). The outcomes of these therapies are currently studied in several hundreds of clinical trials. Remarkable results have already been achieved in certain types of cancer (melanoma, leukemias, lymphomas) for which immunotherapy is now being used as a standard of care.

Besides the desired antitumor effects, immunotherapy can also trigger unique toxicities resulting from excessive immune system activation. These may be restricted to certain organs (colitis, pneumonitis) or be a systemic inflammatory response (cytokine release syndrome [CRS]). When severe, immunotherapy toxicities can be life-threatening and their management may require admission to the ICU for continuous monitoring and supportive care. Intensivists thus increasingly find themselves leading and coordinating multidisciplinary care for complex oncologic patients.

IMMUNE CHECKPOINT INHIBITORS

Immune checkpoint inhibitors are the most commonly administered form of cancer immunotherapy. These agents enhance antitumor activity of the patient's own T cells by blocking certain T-cell inhibitory signals. FDA-approved inhibitors of PD-1 (pembrolizumab, nivolumab), PD-L1 (atezolizumab, avelumab, durvalumab), and CTLA-4 (ipilimumab) are used in treatments of various solid tumors including melanoma, non-small-cell lung cancer, head and neck squamous cancers, and renal cell carcinoma. These agents can produce a unique set of side effects termed immune-related adverse events, which may be dermatologic, gastrointestinal, hepatic, endocrine, pulmonary, cardiac, or neurologic inflammatory complications. These side effects typically manifest weeks to months after initiation of the therapy.

The mainstay of the management in cases of moderate- and high-grade toxicity is the interruption of the checkpoint inhibitor and administration of corticosteroids. Tumor necrosis factor-α antagonists have been used in cases refractory to steroids. ICU monitoring and supportive care may be required in cases of severe pneumonitis (oxygen therapy, mechanical ventilation), myocarditis (inotropic support, antiarrhythmics), severe enterocolitis (fluid and electrolyte repletion), liver failure, and adrenal insufficiency. Echocardiography should be performed in patients with new onset dyspnea, pulmonary edema, or hypotension. Patients receiving prolonged immunosuppression for the treatment of checkpoint inhibitor toxicity are at an especially high risk of infectious complications (opportunistic infections, sepsis).[200]

CHIMERIC ANTIGEN RECEPTOR T CELLS

CAR T cells are genetically engineered T cells that have the ability to bind to target tumor cells, undergo supraphysiologic activation, and cause tumor cell lysis. Upon completion of an *ex vivo* manufacturing process, CAR T cells are infused into patients and patients typically remain monitored for several days in the hospital setting. Currently, CAR T cells are used in the treatment of certain relapsed/refractory hematologic malignancies (leukemias, lymphomas, multiple myeloma) but clinical trials in patients with solid tumors are also ongoing. Two CD19-directed CAR T-cell products for treatment of B-cell malignancies (non-Hodgkin lymphoma, acute lymphoblastic leukemia) have been FDA approved and cases of complete disease remission have been reported.

However, CAR T-cell therapy is frequently associated with toxicities that can range from minor (fatigue, fever, myalgias) to life-threatening (shock, multiple organ dysfunction). These toxicities are primarily driven by proinflammatory cytokines (IL-6, IFNγ) that are released upon CAR T cell–tumor cell interaction. Of importance to ICU clinicians are severe forms of CRS and neurotoxicity, which require ICU monitoring and management. CRS typically manifests within several days after CAR T-cell infusion by a spectrum of fever, tachycardia, hypotension, or respiratory insufficiency. The onset of neurotoxicity (encephalopathy, aphasia, or seizures) can be delayed and is not necessarily preceded by clinically significant CRS. Fatal cases of diffuse cerebral edema have been reported.

The mainstay of the therapy of severe forms of CRS is the administration of antiinflammatory agents (IL-6 antagonists, corticosteroids) in conjunction with individualized supportive care (fluid resuscitation, vasopressors, mechanical ventilation, renal replacement therapy). Neurotoxicity is treated with anticonvulsants and corticosteroids. It is crucial that other precipitating factors of neurologic, hemodynamic, or respiratory decline that are common in patients with advanced cancer are always actively excluded. Sepsis, which often resembles CRS, is a frequent cause of morbidity and mortality in this patient population.[201,202]

Point-of-Care Ultrasound in Critical Care

As a result of improving technology, decreasing cost, and widening availability, the use of point-of-care ultrasound (POCUS) has taken an increasing role in the practice of critical care. The uses of ultrasound in the critically ill are manifold, from vascular access to cardiopulmonary evaluation. POCUS allows for rapid and repeated assessments of the critically ill patient at the bedside to augment traditional physical examination and physiologic monitors. Because techniques and technologies continue to evolve, there are a multitude of published protocols. Although the exact protocol used is of less significance, the specific skills and applications of ultrasound will likely become a core competency in the ICU.[203,204] Ultimately, ultrasound is another tool in the armamentarium of the intensivist that requires understanding of physiology and expert clinical decision making for safe and beneficial use.

VASCULAR ULTRASOUND

Vascular cannulation is a vital skill in the ICU. Ultrasound guidance can be used before the procedure to confirm anatomy and vessel patency or, preferentially, it can be used in real time during the procedure. There are different techniques, the two most common being out-of-plane needle insertion with short axis view of the vessel, or in-plane needle insertion with a long axis view of the vessel. Ultrasound can be used for cannulating central venous structures, arteries, or even peripheral veins.

Central venous access is one of the most common procedures in the ICU. The use of ultrasound imaging to assist catheter insertion is a Grade 1B recommendation by the SCCM guidelines.[203,205] For the cannulation of the internal jugular or femoral veins, SCCM offers an even stronger Grade 1A recommendation.[206] For other central venous cannulation sites, such as the subclavian or axillary, ultrasound guidance may still improve success and reduce complications, but the evidence is not as definitive.[207] Specific recommendations are given for the use of real-time imaging in the short axis when using ultrasound; however, the conclusions are weaker.[208,209] Although the long-axis ultrasound view of vessels can have benefits such as reducing posterior wall puncture, the short-axis orientation affords a view of surrounding structures, requires less training, and has been shown to have a higher success rate in some studies.[210]

Arterial cannulation is another extremely common procedure in the ICU and the use of ultrasound guidance is a Grade 2B recommendation.[203] A recent meta-analysis of randomized control trials concluded real-time ultrasound guidance decreased time to cannulation and hematoma formation.[211] A study of radial arterial access for cardiac catheterization also demonstrated ultrasound significantly decreased the frequency of "difficult access" requiring greater than five attempts or 5 minutes.[212] Given the high incidence of difficult access in critically ill patients, due to peripheral edema, peripheral vascular disease, and weak pulses, ultrasound guidance for arterial cannulation is likely even more valuable in the ICU compared to other settings.

Deep venous thrombosis (DVT) is a common complication in postsurgical and ICU patients that can have serious sequelae including pulmonary embolism. Diagnosis of DVT is traditionally made by a sonographer-performed vascular examination with formal interpretation by a specialist. In contrast, examination with POCUS by a critical care physician can reduce time to diagnosis and be performed when sonographers are unavailable. By using 2D ultrasound to examine the popliteal artery and femoral veins for compressibility along their length, proximal DVTs can be readily diagnosed at the bedside. In one study, a sensitivity and specificity of 86% and 96%, respectively, was achieved even with inexperienced practitioners.[213] Ultrasound screening for DVT by an intensivist is a Grade 1B recommendation in SCCM guidelines.[203]

PULMONARY ULTRASOUND

Ultrasound examination of the lung can be used to identify and manage many pathologies in the ICU.[214] Normal lung is well aerated and does not transmit ultrasound. When imaging healthy lung, only the pleural line is visualized and anything beyond the pleural line is noise or artifact. However, changes or loss in these characteristic ultrasound artifacts can be used to identify pathology.

Three artifacts are expected in normal lung ultrasound: A-lines, lung sliding, and B-lines. A-lines are regularly spaced repeats of the pleural line that appear as horizontal lines deep to the true pleural line. These are artifacts created by reverberations between pleural line and soft tissue. "Lung sliding" artifact is a shimmering of the pleural line that has been described as "ants walking on a twig" that also causes shifting graininess beyond the pleural line. This is created by the sliding of the parietal and visceral pleura of the lung against each other. The M-mode corollary of lung sliding is the "sandy beach" sign, where the soft tissue above pleura appears as stable horizontal lines, "sky," and below the pleural line a grainy pattern of "a sandy beach" due to lung sliding artifact. See Fig. 83.1 for an example of M-mode appearance of normal lung. "B-lines" are a third kind of artifact occasionally seen in normal lung. They are vertical streaks that radiate down from the pleural line to the far field image. Sometimes called "comet tails" or "pleural rockets," they are caused by fine reverberation within interlobular septae. One or two B-lines in a rib space can be normal, especially in the dependent lung fields.[215,216]

Pneumothorax is a common pathology in the ICU and can rapidly be diagnosed by ultrasound. Pneumothorax is readily identified on ultrasound by loss of lung sliding artifact and absence of B-lines due to loss of contact between the pleural surfaces. There may also be the predominance of A-lines, since they arise between the pleura and soft tissue. If M-mode is applied, there is loss of the "sandy beach" sign and the entire field appears as stable horizontal lines that has been called the "bar code" sign. Ultrasound is very sensitive and highly specific in the diagnosis of pneumothorax and consistently outperforms supine chest x-ray.[217] Poor image quality and concurrent pathologies, such as adhesions or bronchial intubation that prevent sliding of the lung pleura, may result in false positives. However, the presence of "lung point," a transition point between lung sliding and nonsliding, conferred a specificity of 100% compared to chest computed tomography in some studies.[218] The use of ultrasound for diagnosis of pneumothorax is a Grade 1A recommendation by the SCCM.[203]

Pleural effusions are easily visualized by ultrasound. Since effusions are fluids, they efficiently transmit ultrasound and

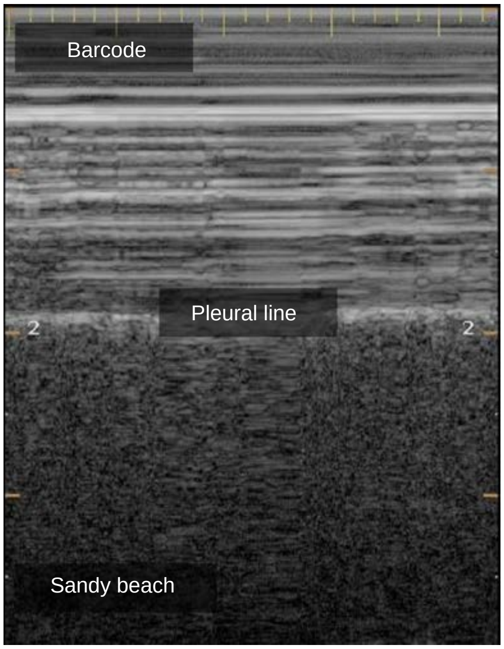

Fig. 83.1 An M-mode ultrasound tracing of normal lung. The near field at the top of the image is dominated by a pattern of horizontal lines created by the relatively still soft tissue above the lung pleura. At 2 cm depth is the pleural line, and below this there is a grainy pattern created by the lung sliding artifact of normally aerated lung. This creates the "sandy beach" sign where the linear pattern of soft tissue is the "sky" above the grainy "beach" pattern created by normal lung sliding.

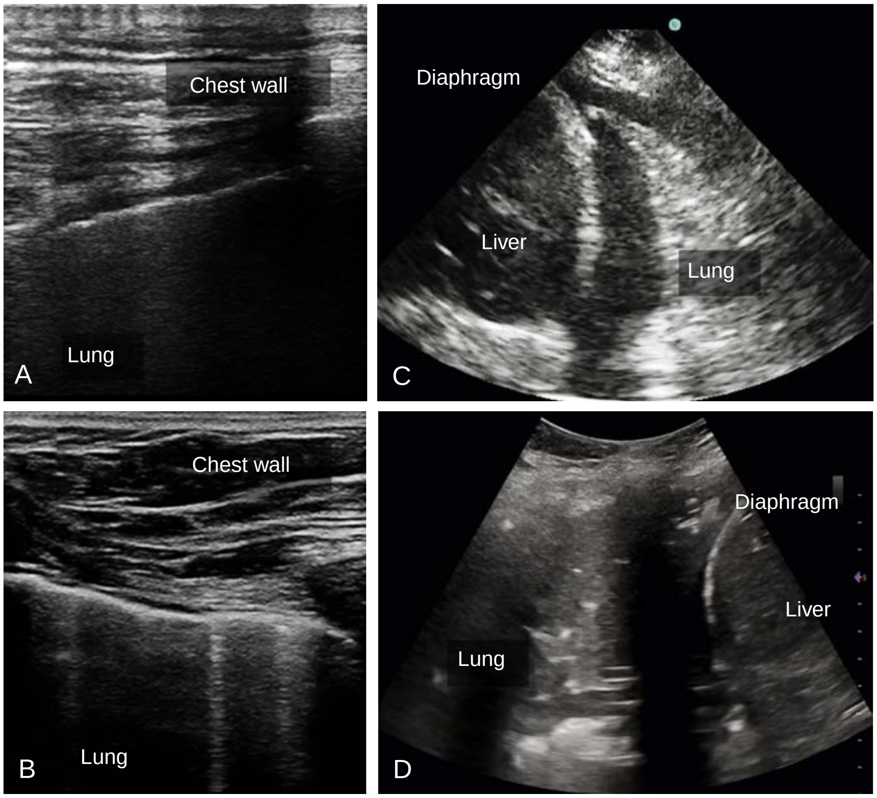

Fig. 83.2 Common lung ultrasound pathologies. (A) Normal lung ultrasound. (B) Atelectatic lung in a pleural effusion. (C) Confluent B-lines indicative of alveolar syndromes like severe pulmonary edema or diffuse alveolar hemorrhage. (D) Consolidated lung with hyperechoic air bronchograms seen in pneumonia or acute respiratory distress syndrome.

appear as a hypoechoic area below the pleural line that allows imaging of deeper structures. They are usually best imaged in the dependent regions from the posterior axillary line. Atelectatic lung can often be seen floating in larger effusions. See (Lung-Fig. 83.2) for an example.[215,216] Loculations with the effusion can also be identified with ultrasound imaging. Compared to traditional chest radiographs, POCUS has been shown to be equivalent or superior in the diagnosis of pleural effusion and allows for quantification and localization. Effusions of greater than 5 cm from the anterior pleural line to lung have been associated with volumes greater than 500 mL.[216] The use of ultrasound for pleural effusions diagnosis is Grade 1A recommendation and Grade 1B recommendation for thoracentesis guidance by the SCCM.[203]

Alveolar-interstitial syndrome occurs in conditions such as pulmonary edema, pneumonia, and ARDS. This can be seen on ultrasound by progressively increasing number, density, and confluence of B-lines. Greater than three B-lines in one rib space is considered pathologic, and indicates thickening of the interlobular septae from edema or alveolar edema. In severe consolidation and atelectasis, aeration is lost and ultrasound is transmitted through the tissue. On ultrasound imaging, the lung has liver-like appearance (hepatization), sometimes with visible air bronchograms and blood vessels.

All these ultrasound findings, in combination with other findings, have been combined into effective protocols such as the BLUE-protocol to differentiate between pulmonary pathologies in critically ill patients.[215,216,219] For example, a COPD exacerbation would be characterized by relatively normal lung ultrasound. In comparison, cardiogenic pulmonary edema from congestive heart failure would be dominated by increased B-lines from interstitial edema and pleural effusions. Pneumonia and ARDS on ultrasound may be characterized by increased B-lines, consolidation, and decreased lung sliding due to exudative adhesions.[220] A recent meta-analysis suggests that ultrasound can accurately diagnose pneumonia; however, further research needs to be performed on the broader use of POCUS with alveolar and interstitial disease. Its use is a Grade 2B recommendation.[203,221] See Figs. 83.2*A-D* for examples of the ultrasound appearance of common pathologies.

CARDIAC ULTRASOUND

Cardiac ultrasound performed by critical care physicians has gone by many names including "focused cardiac ultrasound," "point-of-care echocardiography," "bedside cardiac ultrasound," and "critical care echocardiography (CCE)."[204,222] Regardless of the name, ultrasound assessment of cardiac structures by critical care physicians can rapidly identify many relevant findings in the unstable patient. These include: left ventricular systolic dysfunction or dilation, right ventricular systolic dysfunction or dilation, pericardial effusions, inference of elevated filling pressures, predictions of volume responsiveness, gross intracardiac masses, and severe valvular pathology.[204,214,223-225] For further details, refer to Chapter 37 on Perioperative Echocardiography.

TABLE 83.3 A Table of Contrasting Common Point-of-Care Cardiac Ultrasound Findings in Different Shock States

Category	Shock Type	LV Function	RV Function	Pericardial Effusion	Inferior Vena Cava	Lung Sliding	Lung B-lines	RVSP	CO/VTI	Valvular dysfunction
Afterload	Distributive	↑	↑	–	…	+	–	–	High	–
Preload	Hypovolemic	↑	↑	–	Collapsed	+	–	–	Low	–
Cardiogenic	LV Failure	↓	↑/↓	–	Distended	+	+	↑	Low	–
	RV Failure	↑	↓	–	Distended	+	–	↑/↓	Low	–
	Acute Coronary Syndrome	WMA	↑/↓	–	Distended	+	+	↑	Low	–
	Valvular	↑/↓	↑/↓	–	Distended	+	+/–	↑	Low	+
Obstructive	Tamponade	↑	↑	+	Distended	+	–	–	Low	–
	Pneumothorax	↑	↑	–	Distended	–	–	–	Low	–

Isolated signs are likely not specific or sensitive, especially in mixed shock states. Findings must be correlated to the clinical and physiological situation.
CO, Cardiac output; *LV*, left ventricle; *RV*, right ventricle; *VTI,* volume-time integral; *WMA*, wall motion abnormalities.

Ultrasound evaluation of cardiac and related structures allows for the rapid assessment of patients in undifferentiated shock and has been shown to be more accurate in diagnosing cardiac pathology than physical examination.[225] Information gained when integrated with other clinical information can be used to quickly narrow the differential diagnosis. Table 83.3 gives common findings in different shock states. Cardiac ultrasound during cardiac arrest and cardiopulmonary resuscitation is a valuable tool that can provide key information.[214,225] Furthermore, since the examination is performed by the bedside critical care physician, assessments can be repeated to monitor and evaluate response to therapies.

OTHER APPLICATIONS AND THE FUTURE

Critical care ultrasound is a rapidly developing field. Research continues and more applications are being explored. This includes ultrasound of the optic nerve to evaluate for elevated intracranial pressures, abdominal ultrasound, diaphragmatic ultrasound for ventilator weaning, lung ultrasound for fluid resuscitation, gastric ultrasound, airway ultrasound, and others.[219,226-228] Ultimately, more clinical trials will need to be performed to evaluate the utility of each of these techniques when compared to traditional modalities. Currently, there is a lack of strong clinical outcomes evidence of POCUS, with one prospective emergency department study showing no benefit in patients presenting with hypotension.[229] However, given the advantage of POCUS, many of them will likely find a valuable place in critical care.

Conclusion

Critical care medicine is an exciting and rapidly evolving field that involves the care of a wide variety of patients with life-threatening syndromes regardless of the primary physiologic insult. Effective critical care requires a collaborative, interprofessional approach that utilizes highly developed systems and protocols of care to ensure consistent and high-quality care. Intensivists specialize in the application of advanced life support therapeutics and help lead multidisciplinary care teams in the delivery of patient- and family-centered care.

Acknowledgment

This chapter is a consolidation of two chapters in the 8th edition, Chapter 101 Critical Care Anesthesiology and Chapter 106 Nutrition and Metabolomics. The editors and publisher would like to thank the following authors: Linda Liu, Michael Gropper, and Charles Weissman for their contributions to the prior edition of this work. It has served as the foundation for the current chapter.

84 Neurocritical Care

NERISSA U. KO and KRISTIN ENGELHARD

KEY POINTS

- Critical care of the nervous system is based on control of cerebral and spinal cord physiology and the prevention of secondary insults. This goal, in turn, depends on the comprehensive maintenance and adequacy of physiologic parameters and organ function.
- Cerebral function is critically dependent on oxygen delivery matching metabolism.
- Increased intracranial volume beyond the capacity of compensatory mechanisms increases intracranial pressure (ICP) and may diminish perfusion adversely. The resulting cellular energy failure both initiates and propagates edema and inflammation.
- The resolution of cerebral edema depends on hydrostatic and osmolar forces applied to the blood-brain barrier. Excess perfusion pressure or intravascular hypotonicity worsens edema and must be avoided.
- Blood-brain barrier disruption varies over time and by pathologic process, and it affects the ability of hypertonic agents to exert a beneficial osmotic effect.
- Fever is frequently overlooked in the neurocritical care unit, but it significantly affects patient outcomes across a range of pathologic processes.
- Neurologic monitoring comprises placement of appropriate monitoring devices as well as prompt response and institution of therapy to the changes detected. The goal is to optimize the physiologic environment. Clinical examination of neurologic function remains a crucial part of monitoring and care.
- The main principle in the treatment of traumatic brain injury involves the control of physiologic parameters such as ICP to achieve an adequate cerebral perfusion pressure. No pharmacological intervention exists to minimize secondary brain damage.
- After the initial hemorrhage and early brain injury, mortality and morbidity from subarachnoid hemorrhage (SAH) arise from rebleeding and delayed cerebral ischemia. Early treatments of ruptured aneurysms, including medical and endovascular therapies, to improve cerebral perfusion, maintain blood volume, and optimize oxygen delivery have improved outcomes. SAH may be accompanied by significant pulmonary, cardiovascular, or endocrine effects.
- Successful therapy for ischemic stroke is contingent on a time window of viability. Urgent assessment and rapid treatment are crucial to a good outcome. Endovascular therapy, in conjunction with advances in imaging, has led to significant outcome benefits.
- Injury to the spinal cord necessitates careful evaluation of respiratory mechanics to assure adequate ventilation.
- Infections of the central nervous system demand an aggressive approach to volume resuscitation, cerebrospinal fluid sampling, and early empiric antibiotic therapy, similar to treatment for sepsis.

Critical care of the central nervous system (CNS) involves collaboration among several disciplines—neurosurgery, anesthesiology, neurology, neuroradiology, and electrophysiology. Each discipline offers unique contributions, which, in partnership, provide optimal care not only to the injured brain but also to the cardiopulmonary, endocrine, gastrointestinal, and renal systems that support cerebral physiology.[1] Integration of the complex goals of this care relies on the physician specializing in neurocritical care. The use of a neurocritical care team, rather than single specialty care, has been associated with reduced in-hospital mortality and the length of stay.[2] Although other specialists can train to be neurointensivists, anesthesiologists with training in neuroanesthesia and critical care are particularly well suited to demonstrate the combination of airway and cardiovascular support skills that, together with an understanding of the physiology and pharmacology of the nervous system, may improve the outcome.

Although the brain has certain preeminence among the organs of the body, it relies on a stable platform of organ function elsewhere to enable homeostatic control and mechanisms of repair and recovery. Injury to the brain is associated with and precipitates a wide spectrum of dysfunction of other organ systems (Box 84.1). Vice versa, brain function can also be perturbed by injury of the other organs. This mutual relationship is best described by the concept of organ crosstalk.[3-5]

Intracranial Physiology and Cerebrovascular Autoregulation

The cerebrovascular circulation is constrained by a rigid perimeter of bone (see also Chapter 11). After exhaustion of limited compensatory mechanisms, the bony confines of the

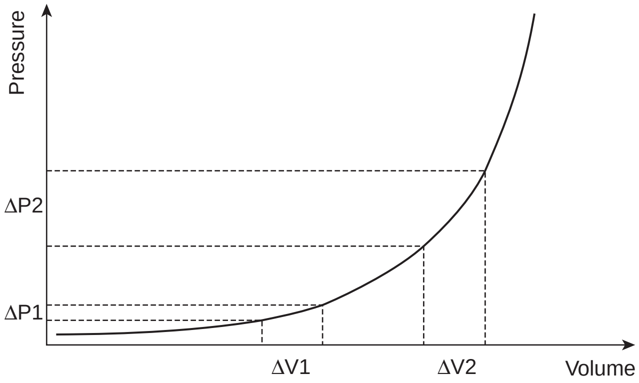

Fig. 84.1 Intracranial pressure-volume relationship: additional intracranial volume *(ΔV1)* is accommodated with minimal change in intracranial pressure *(ΔP1)*. Once this capacity is exhausted, the same increase in volume *(ΔV2)* leads to an exponential rise in intracranial pressure *(ΔP2)*.

skull mandate increasing intracranial pressure (ICP) consequent to increasing intracranial volume. The change in ICP with change in intracranial volume is often referred to as the intracranial compliance curve, but it is more appropriately termed the *intracranial elastance curve* (Fig. 84.1). The increase in elastance (i.e., changes in ICP as a function of changes in intracranial volume) implies poor compliance, and a small change in volume can lead to an inordinate increase in pressure. These changes in volume are due to the increase in intracranial tissue or fluid content (i.e., blood, interstitial fluid/edema, or cerebrospinal fluid [CSF]). Tissue content is relevant insofar as mass lesions influence intracerebral elastance and accentuate the effects of fluid changes. Small increases in volume can be accommodated by an outflow of CSF from the cranial cavity into the spinal canal, producing an exponential pressure-volume relationship (see Fig. 84.1).

The cranial vault is compartmentalized by the falx cerebri and tentorium cerebelli, which creates the possibility of internal pressure gradients (Fig. 84.2). Increased intracranial volume finally leads to herniation of brain tissue through the "apertures" of the compartments. Pressure gradients are initially hydraulically equilibrated, with CSF moving from the ventricular chambers to the extracranial spinal space. Brain herniation may also contribute to impedance of CSF drainage either by occlusion of the foramina of Monro in the case of lateral herniation or by occlusion of the third ventricle and aqueduct by supratentorial herniation through the tentorial gap. This situation typically gives rise to clinical features of midbrain compression. Unilateral pupillary dilation, ipsilateral or even contralateral paralysis (the Kernohan notch phenomenon), and abnormalities of respiration are apparent in the patient. If the herniation continues, it will result in cerebellar descent through the foramen magnum with consequent compression of the brainstem, thus producing bilateral papillary fixation, either tachycardia or bradycardia, and systemic hypertension.[6] Changes in cerebral mass secondary to increase in intracerebral venous blood volume also arise from venous drainage obstruction by compression of the easily susceptible bridging veins draining from cortex to venous sinuses. Once an individual threshold of elastance is crossed, changes in volume exert a mass effect on the draining veins, which act as Starling resistors. This effect decreases drainage, which, in turn, amplifies and prolongs pressure increases. Blood volume increases may be extravascular (i.e., hemorrhage) or intravascular (i.e., accumulation within a predominantly venous capacitance circulation). The other main fluid mass effect is through edema, either cytotoxic or vasogenic.[7] Cytotoxic edema results from hypoxia, with swelling of the intracellular compartment, whereas vasogenic edema in the interstitium usually develops from a breach of the blood-brain-barrier, often in response to high blood pressure.[8]

Changes in the control of cerebral blood volume (CBV) may have significant effects on ICP and, thereby, on cerebral perfusion pressure (CPP). The cerebral vasculature responds to increase in arterial partial pressure of carbon dioxide ($PaCO_2$), decrease of arterial partial pressure of oxygen (PaO_2), and reduced mean arterial pressure (MAP) by dynamically altering arteriolar caliber to maintain a constantly matched cerebral blood flow (CBF) sufficient to meet metabolic demands (Fig. 84.3). Carbon dioxide, as with hydrogen, potassium, calcium, nitric oxide, adenosine, and lactate, are among many purported metabolic mediators of flow.[9] A reduction in substrate delivery (i.e., oxygen and nutrients) to less than the threshold necessary to maintain

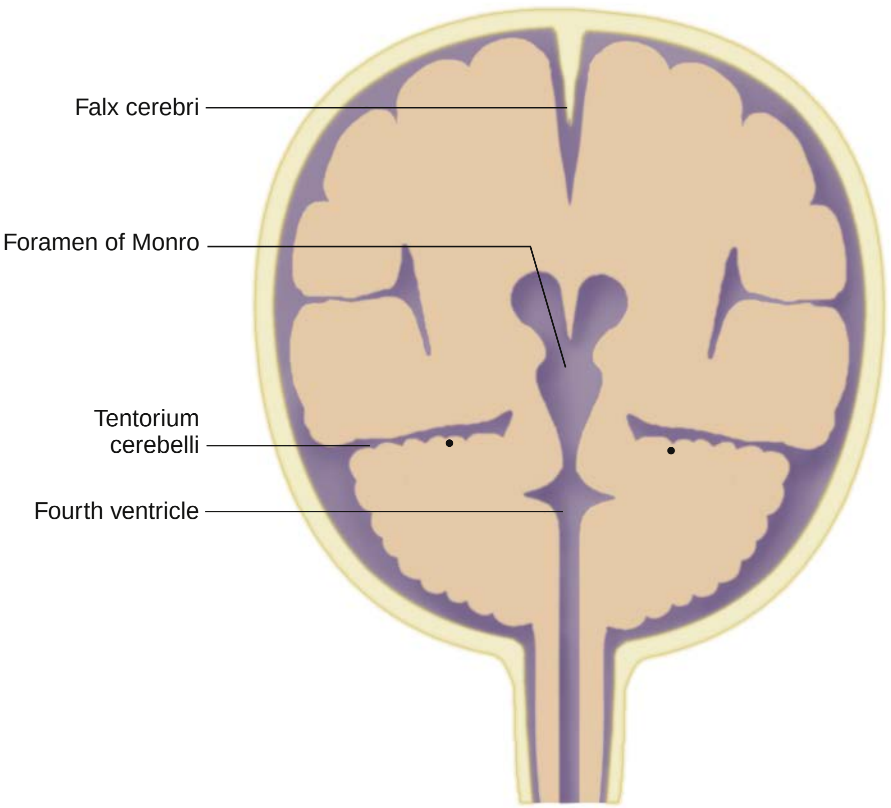

Fig. 84.2 Schematic of intracranial compartments: coronal section.

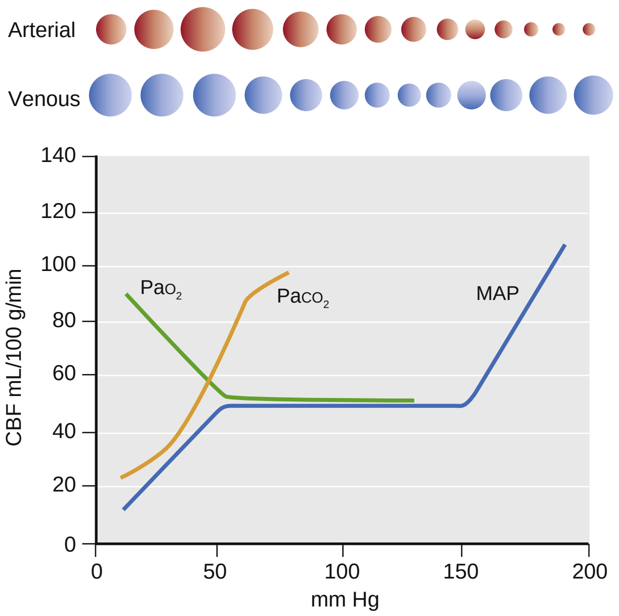

Fig. 84.3 The influence of changes in arterial partial pressure of oxygen *(PaO$_2$)*, arterial partial pressure of carbon dioxide *(PaCO$_2$)*, and mean arterial pressure *(MAP)* upon vessel diameter and cerebral blood flow *(CBF)*.

cellular viability induces cell injury with consecutive cytokine and chemokine release. This inflammatory amplification expands the injury, disrupts the blood-brain barrier function, and may directly lead to apoptosis or necrosis.[10] The disruption of the blood-brain barrier creates vasogenic edema and allows serum proteins to cross into brain parenchyma with prolonged effects. This process is more evident in the high metabolically active gray matter than in white matter.

CBF control may be directly compromised by brain injury or by abnormalities of respiration and arterial blood pressure. Consequently, untoward changes in physiologic parameters, including arterial hypotension, hypoxia, hyper- and hypocapnia, hyper- and hypoglycemia, and fever, as well as seizures, produce what is termed a *secondary physiologic insult.* The *primary injury* is caused by the direct destruction of tissue during the initial trauma or ischemia, while the area of the *secondary injury* slowly extends into the intact tissue and induces further harm to the vulnerable brain and worsens outcome.[11] The control of the secondary brain injury is the target of the development of potential neuroprotection protocols.[12]

General Cardiopulmonary Considerations

Arterial hypotension, especially in combination with hypoxemia, is a well-documented source of cerebral morbidity.[13,14] Therefore, a reduction of cardiac output and CPP have to be avoided to prevent further deterioration of the level of consciousness, which in turn leads to airway compromise and hypercapnia and hypoxia. Hypercapnia, hypoxia, and arterial hypotension lead to autoregulatory cerebral vasodilation, which increases CBV and ICP and further diminishes CPP, perpetuating the vicious circle (Fig. 84.4).

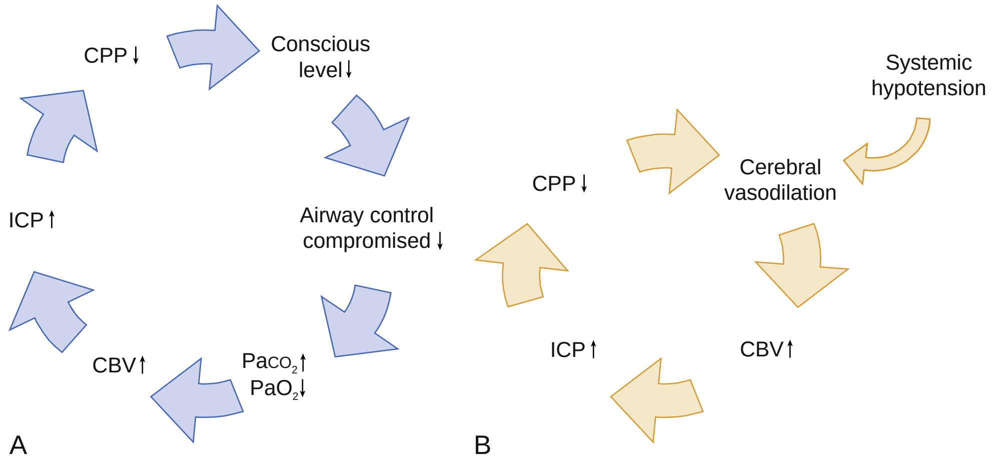

Fig. 84.4 (A) Ventilatory-neurologic circle of dysfunction. Induced changes in partial pressure of carbon dioxide *($PaCO_2$)* and partial pressure of oxygen *(PaO_2)* produce changes in cerebral blood volume *(CBV)*, intracranial pressure *(ICP)*, and cerebral perfusion pressure *(CPP)*. This, in turn, impairs ventilatory control. (B) Hemodynamic-neurologic circle of dysfunction. Similar to the diagram in **(A)**, systemic hypotension induces cerebral vasodilation, which increases CBV and ICP and reduces CPP, which, in turn, increases vasodilation.

Any deterioration in ventilatory efficacy adversely affects cerebral elastance through carbon dioxide-induced vasodilation and leads to hypoxemia, which can cause direct as well as indirect injury to the brain.[14] Arterial hypoxemia, less than 60 mm Hg, is a significant contributor to secondary insult from vasodilatory ICP effects, in addition to reduced oxygen delivery to the cell. Pulmonary compromise is often seen in neurologic patients with altered mental status due to impaired airway reflexes and repeated aspiration episodes, which culminate in a significant incidence of pneumonia, irrespective of the initiating pathologic process.[15,16] Another potential mechanism is the release of cytokines from the brain in response to the inflammatory process triggered by an injury. This release may be sufficient to induce acute respiratory distress syndrome (ARDS) and systemic inflammatory response syndrome (SIRS).[4,17] Conversely, ARDS can also trigger cerebral inflammation by releasing inflammatory mediators like cytokines.[4,17] The ventilatory treatment for ARDS may create a therapeutic dilemma in the presence of cerebral pathophysiology. However, the "open lung" concept (i.e., small tidal volumes, high frequencies, and high positive end-expiratory pressure [PEEP]) developed to minimize alveolar distention and reduce lung injury appears to be feasible in neurosurgical patients, despite theoretic concerns regarding adverse effects on ICP.[18] The use of PEEP up to 15 cm H_2O appears to improve brain tissue oxygen pressure and oxygen saturation without negative effects on ICP or CPP.[19].

Fluids, Electrolytes, and Nutrition

Normally, capillary fluid shift is a function of hydrostatic pressure pushing fluid out and the balance of osmotic forces retaining fluid within[20]:

$$\mathrm{Jv} = \mathrm{Kf}\left([\mathrm{Pc} - \mathrm{Pi}) - \sigma\,[\pi\mathrm{c} - \pi\mathrm{i}]\right)$$

where Jv is the net fluid movement between compartments, Pc is the capillary hydrostatic pressure, Pi is the interstitial hydrostatic pressure, πc is the capillary osmotic pressure, πi is the interstitial osmotic pressure, Kf is the filtration coefficient (this is a product of surface area and hydraulic conductivity), and σ is the reflection coefficient (the membrane impermeability toward osmotically active particles).

In extracranial capillaries, these osmotic forces are derived from oncotic pressure because smaller solutes can cross the capillary basement membrane following concentration gradients and only large protein molecules remain to exert their effect. However, in the brain, because of the presence of tight junctions in the endothelium, the intact blood-brain barrier reflects smaller solutes (e.g., sodium and chloride ions), and this relative impermeability renders cerebral capillary fluid shift a function of hydrostatic and *total* osmolar forces, with the oncotic pressure being responsible for only 1 mOsmol/kg.[21] Therefore, the fluid shift in the cerebral capillaries is most dependent on the osmolar gradient. In the absence of externally administered osmotically active substances (e.g., mannitol), plasma osmolality is 280 to 300 mOsm/kg and is almost entirely determined by sodium concentration.

$$\text{Plasma osmolality} = [\text{NA}]_{\text{serum}} \times 2 + \text{glucose}/18 + \text{BUN}/2.8$$

where Na is sodium and BUN is blood urea nitrogen.

As a reduction of plasma osmolality of 4 to 5 mOsm/kg increases cerebral edema, hypotonic solutions must not be used in the neurosurgical patient. Table 84.1 shows that the mean measured osmolality is often lower than the calculated osmolarity.[21] Hence, intravascular fluid therapy must be carefully considered under circumstances of cerebral ischemia and inflammation. The brain exerts homeostatic control on metabolic and endocrine activity, and neurologic dysfunction can manifest as untoward changes in fluid and electrolyte balance. Diabetes insipidus is a florid example of this, with polyuria, subsequent hypovolemia, and, if the disorder is left untreated, systemic hypotension. Iatrogenic causes may include the use of osmotic diuretics. Sympathetic denervation stemming from brainstem or spinal cord injury (SCI) may also contribute to reductions in venous return due to increased vasodilation and peripheral venous pooling.[22]

TABLE 84.1 Osmolarity and Osmolality of Commonly Used Intravenous Fluids

Fluid	Mean Measured Osmolality (mOsm/kg)	Theoretical Osmolarity (mOsm/L)
Plasma	288 [280-300]	291
Isotonic saline 0.9%	285 [282-286]	308
Ringer´s lactate solution	257 [257-258]	276
Gelatin 4%	271 [270-272]	274
Human albumin (4%)	266 [266-267]	274.4

Nutritional deficits occur often in brain injured critically ill patients, and greater energy and protein deficits are associated with prolonged intensive care unit (ICU) and hospital stays.[23] According to the Brain Trauma Foundation (BTF), early enteral nutrition should be initiated at least by the fifth day and at most by the seventh day post injury.[24] It is possible that an even earlier start at day one after trauma can be beneficial in terms of better control of infection and overall complications.[25] For administration of enteral nutrition, a transgastric jejunal tube is recommended to reduce the incidences of ventilator-associated pneumonia.[24]

Stress-induced hyperglycemia is associated with higher morbidity and mortality in patients with neuronal injury,[26] but tight glycemic control, targeting plasma glucose levels of 80 to 120 mg/dL, increased the risk of hypoglycemia and did not improve outcomes compared to conventional therapy allowing a maximal glucose concentration of 150 mg/dL.[27] Therefore, moderate glycemic control with a target blood glucose level of 110 to 150 mg/dL is advocated.

Temperature Control

Fever occurs with an incidence of up to 70% in brain injured patients.[28] The degree and duration of early hyperthermia are closely correlated with a higher morbidity and mortality after neurologic injury.[29] The temperature threshold that produces progressive thermal injury to the metabolically active brain cells, blood-brain barrier, and vascular endothelium appears to be between 39°C and 40°C.[30] Hyperthermia, an often overlooked insult to the compromised brain, increases oxygen utilization and metabolic stress.[29,31] Patients in the ICU can have multiple risk factors for hyperthermia such as infection from indwelling catheters (e.g., arterial, venous, CSF) or lung injury.[31] However, in up to one-third of cases, the cause of the fever remains unexplained and often is classified as central fever.[28]

The concept of targeted temperature management in neurocritical care includes therapeutic mild hypothermia, controlled normothermia, and aggressive treatment of fever.[32] Although in head trauma patients, induced mild or moderate hypothermia failed to improve outcome, hypothermia did improve neurologic outcome in neonates with hypoxic-ischemic encephalopathy and in patients after out-of-hospital cardiac arrest.[33-35] To cool patients, gel pads or intravascular temperature-modulating devices with servo-controls should be used to minimize overshoot. Cold saline infusions are additionally recommended.[32] Core temperature should be monitored continuously using an esophageal temperature probe or a bladder temperature probe.[32] Shivering must be treated promptly with nonsedating interventions (e.g., acetaminophen) instead of narcotic analgesics, sedatives, or paralytics.

Monitoring

The avoidance or correction of secondary brain damage necessitates the use of physiologic monitors to guide individualized therapy. The most important neuromonitoring devices are shown in Fig. 84.5 (see Chapter 39).[36-39] Neuromonitoring does not obviate the need for regular neurologic clinical examination. Similarly, attention should be paid to the basics of volume status evaluation, cardiovascular stability, respiratory care, and metabolic consumption. Monitors (e.g., processed electrical activity, cerebral oxygenation, and ICP) are merely surrogates of actual integrity of brain tissue and cerebral function.

CLINICAL EXAMINATION

Comprehensive neurocritical care encompasses the ability to perform a competent neurologic examination. Reproducible and objective assessment of neurologic function is as important as some of the sophisticated technology mentioned later, with the advantage that it offers better insight into global nervous system function and allows integration of information in an inherently complex dynamic system. One of the most basic yet important examinations is the pupillary light reflex, the unilateral absence of which may indicate midbrain compression from uncal herniation, which is a neurologic emergency. Bilaterally absent pupillary reflexes signify imminent or established cerebellar herniation, but this may be reversible with rapid efficacious treatment.

Clinical scales have been devised for common neurologic settings. The Glasgow Coma Scale (GCS) is a well-known, universally applied scale (Table 84.2).[40] It relies on independent assessment of eye opening, speech, and best motor movement in response to progressive trials of command, voice, and noxious stimuli. Its accuracy is compromised by the use of sedatives/anesthetics. In clinical practice, duration of loss of consciousness, altered consciousness, and posttraumatic amnesia are also considered. The World Federation of Neurologic Surgeons (WFNS) scale is the preferred rating because it uses the more prevalent GCS but with a modifying component for focal deficit (Table 84.3). The Hunt and Hess Scale describes the severity of subarachnoid hemorrhages and is used as an outcome predictor (Table 84.4).[41,42] Knowing and using these scales are crucial to understanding the terminology and practice of neurocritical care.

INTRACRANIAL PRESSURE AND CEREBRAL PERFUSION PRESSURE

Intracranial Pressure

Increased ICP after head trauma is an important and well-established indicator of secondary brain injury and is

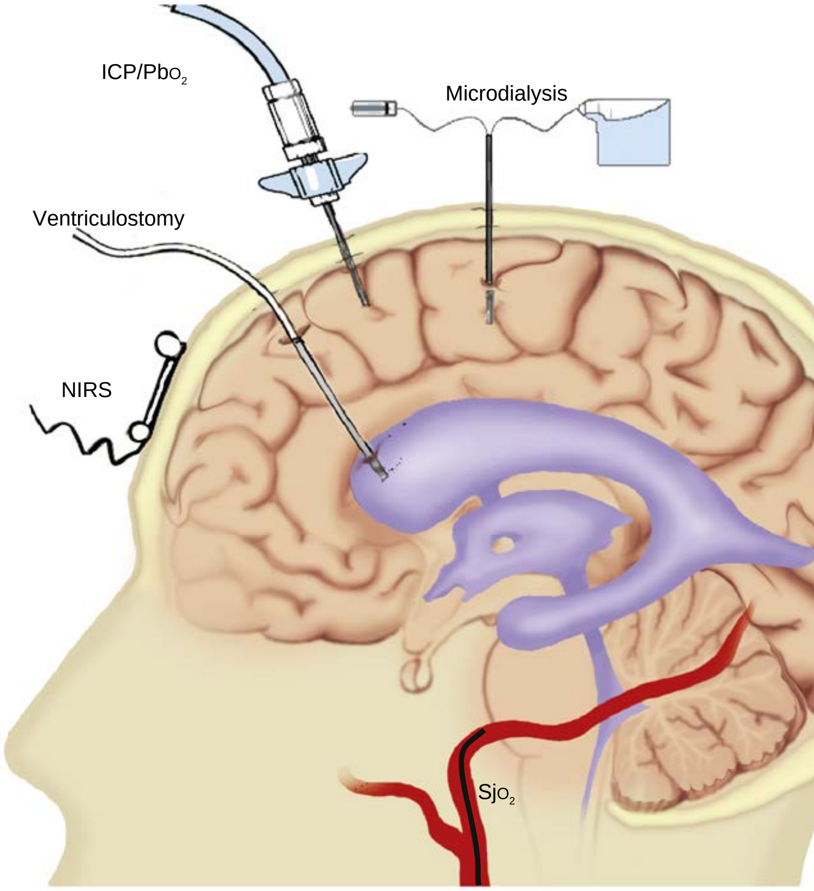

Fig. 84.5 Schematic of available intracranial monitoring, with near-infrared oximetry *(NIRS)*, intracranial pressure (*ICP*, either by ventriculostomy or parenchymal probe), brain tissue oximetry *(Pbo$_2$)*, microdialysis, and jugular venous oximetry *(Sjo$_2$)*.

associated with higher mortality and poor long-term outcome, especially when it is refractory to treatment.[36,43-46] However, the clinical benefit of ICP monitoring is still under discussion.[47-51] The indications for ICP monitoring (e.g., severe head trauma and abnormal computed tomography [CT] scan) and the recommended ICP threshold of 22 mm Hg given in the guidelines are more expert- than evidence-based.[24,52] The sole randomized clinical trial evaluating the potential benefit of ICP monitoring revealed that ICP monitoring does not influence long-term outcome after head trauma.[47] However, ICP-guided therapy in the context of duration of elevated ICP or in combination with information from other neuromonitoring devices may allow for individualized therapy of brain-injured patients and, thereby, improve outcome.[36] For example, the cumulative ICP-time burden with an ICP of 20 mm Hg for longer than 37 minutes diminishes outcome, whereas shorter periods had no adverse effects.[53] Impaired cerebrovascular autoregulation or a CPP below 50 mm Hg reduces the ability to tolerate an elevated ICP.[53]

In clinical practice, two different methods of monitoring ICP are used: microtransducer devices (strain gauge or fiberoptic types) and ventricular catheters.[54] Microtransducer systems are less invasive and easier to place, but they cannot drain CSF and may represent only the compartment pressure where they were placed (see Fig. 84.5).[55] The ventricular catheter is still the “gold standard” of measurement, as long as the ventricles are accessible, because they reflect global ICP and allow therapeutic drainage of CSF. However, they have an increased risk of complications, such as bleeding or infection.[54] Currently, noninvasive ICP measurements are not sufficiently reliable and cannot monitor the dynamics continuously, and, thus, are of research interest only.[36]

Cerebral Perfusion Pressure

The difference between MAP (zero reference point at the tragus of the ear) and the ICP describes the CPP. However, many interventions to decrease ICP, such as head elevation or barbiturate coma, suppress MAP and therefore, may also lower CPP. Most guidelines recommend CPP should be kept between 60 and 70 mm Hg, as higher or lower values worsen outcome after head trauma.[24,44] Recently, the concept of targeting an individualized optimal CPP was introduced, suggesting that an optimal CPP can be calculated for each patient, leading to a more favorable outcome compared with the standard threshold.[56]

CEREBRAL BLOOD FLOW

A constant, uninterrupted CBF is pivotal for the brain, as it has no storage for energy or oxygen. A decrease in CBF below 20 mL/100 g/min causes functional impairment (Table 84.5). Further reductions in CBF lead to structural damage of brain tissue. Modern imaging techniques such as CT perfusion or positron emission tomography (PET)

15	Isoelectric EEG
6-15	Ischemic penumbra
<6	Neuronal death

CBF, Cerebral blood flow; *EEG*, electroencephalogram.

provide detailed information about cerebral hemodynamics, but cannot clinically be used for continuous monitoring of CBF.[36] Therefore, bedside solutions for continuous CBF measurement are necessary.

Thermal Diffusion Flowmetry

Thermal diffusion flowmetry is an invasive, continuous, and quantitative technique to measure local CBF. The thermal diffusion flowmetry catheter measures the temperature difference between a thermistor, which is heated some degrees above tissue temperature, and a temperature probe. The temperature difference can be converted to an absolute measurement of CBF in mL/100 g/min. The catheter is placed in areas at risk for hypoperfusion and can further help detect intracerebral vasospasm and assess cerebrovascular autoregulation.[57] However, there are still concerns about the validity of using thermal diffusion flowmetry long-term, as monitor dysfunctions secondary to placement errors and missing data during recalibration occur.[58]

Transcranial Doppler Monitoring

Transcranial Doppler monitoring is a noninvasive method that uses the Doppler shift effect to assess flow velocity in insonated cerebral arteries. Flow velocity has a linear relationship to CBF as long as the vessel's cross-sectional area and the angle of insonation remain constant.[59] This technique can continuously monitor flow velocity within the main components of the circle of Willis through the ophthalmic, temporal, and foramen magnum acoustic windows.[60] It has excellent temporal resolution and can detect inadequate CBF, assess pressure autoregulation and carbon dioxide reactivity, and can help predict outcome in patients with head trauma.[60,61] Changes in velocity can be used to assess alterations of vascular caliber (e.g., arterial vasospasm) or vascular stenosis.[60] High flow velocities in the middle cerebral artery (MCA) can be caused by vasospasm or hyperemia. This can be distinguished by calculating the ratio between the MCA and the extracranial carotid artery flow velocity (the Lindegaard index).[60]

CEREBROVASCULAR AUTOREGULATION AND VASOMOTOR REACTIVITY

Monitors of CBF can assess the response of the cerebral vasculature to changes in metabolism and blood pressure (i.e., cerebrovascular autoregulation).[62] Static cerebrovascular autoregulation can be determined with sustained blood pressure manipulation by using either a tilt test or a direct vasopressor, whereas dynamic cerebrovascular autoregulation can be assessed using rapid deflation of thigh cuffs that have been inflated above systolic blood pressure (SBP). For continuous assessment of cerebrovascular autoregulation the pressure reactivity index is an established tool. Using the Pearson correlation coefficient the pressure curves of ICP and arterial blood pressure are correlated, calculating an index between -1 and +1.[56]

Instead of ICP other parameters like the CBF (measured by TCD), the brain tissue PO_2, or Near Infrared Spectroscopy (NIRS) derived variables can be used to calculate an autoregulatory index to assess the status of the cerebral autoregulation.[63-67] The presence or lack of autoregulation may guide subsequent treatment and prognosis because the loss of autoregulation is associated with a poor outcome frequently.[68]

CEREBRAL OXYGENATION

To assess the adequacy of cerebral perfusion, measurement of cerebral oxygenation is indicated, because it gives the balance between cerebral oxygen delivery and utilization.

Jugular Venous Oxygen Saturation

The Fick principle may be reversed to examine the venous oxygen saturation which, assuming a constant hematocrit and metabolism, can offer an assessment of the adequacy of CBF and associated oxygen delivery relative to cerebral oxygen consumption:

$$\text{If } AVDO_2 = (CMRO_2/CBF),$$
$$\text{then } CaO_2 - CjvO_2 = (CMRO_2/CBF)$$

Ignoring the contribution of dissolved oxygen, then:

$$(SaO_2 - SjvO_2) \times Hgb \times 1.34 = (CMRO_2/CBF)$$

where $AVDO_2$ is the arteriovenous oxygen content difference; $CMRO_2$ is the cerebral oxygen metabolic rate; CaO_2, $CjvO_2$, SaO_2, and $SjvO_2$ are the arterial oxygen and jugular venous oxygen contents and saturations, respectively; Hgb is the hemoglobin concentration; and 1.34 is the oxygen affinity constant.

In vivo, catheters to measure $SjvO_2$ are placed in retrograde fashion through the internal jugular vein to its jugular bulb at the foramen, or even beyond, to the large sinuses (Fig. 84.6). $SjvO_2$ can be measured intermittently by sampling venous blood from a catheter or continuously by fiberoptic measurement. The normal range of $SjvO_2$ lies between 55% and 75%. Both desaturation (<50%, suggesting inadequate delivery or excess consumption) and abnormally high saturation (>75%, suggesting hyperemia or stroke) have been associated with poor outcomes.[24,69] The arteriovenous oxygen content difference is possibly a more accurate assessment of the adequacy of flow and predictor of outcome.[70] Jugular venous oximetry is sometimes insensitive to focal changes because it reflects the averaged global cerebral venous oxygen saturation from the confluence of hemispheric venous drainage. Consequently, some authors have suggested using oxygen consumption in combination with the cerebral arteriovenous gradient of lactate to make stoichiometric assessments of aerobic versus anaerobic metabolism.[71] The idea is to base goal-directed therapy on metabolic indices ($SjvO_2$) rather than on hemodynamic indices (ICP and CPP).[72] However, due to technical problems (e.g., displacement of catheter) and its low sensitivity, the clinical use of jugular venous oximetry has decreased in favor of alternative monitoring methods for brain tissue oxygen monitoring.[73]

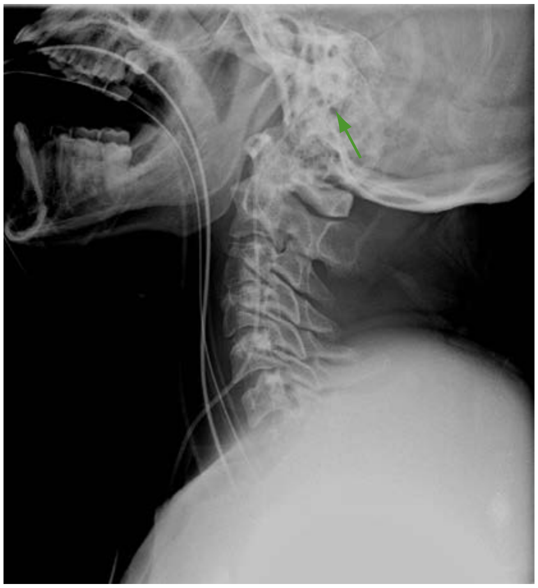

Fig. 84.6 Lateral cervical spine radiograph showing appropriate positioning of the jugular venous oximetry catheter above the lower border of the C1 vertebra (the *arrow tip* is actually within the jugular foramen).

Brain Tissue Oxygen Tension

Miniaturized Clark electrodes have been developed and combined with ICP catheters to provide simultaneous measurements of brain tissue oxygen tension (PbO_2) and ICP. The PbO_2 should be measured in the area of risk, which contains still viable subcortical white matter.[74]The normal range of PbO_2 lies between 20 and 45 mm Hg. In clinical settings, values less than 15 to 20 mm Hg are considered as cerebral ischemia and below 10 mm Hg as severe ischemia.[75] Several studies have demonstrated a correlation between low PbO_2 and poor outcome after traumatic brain injury (TBI). Therapy guided by combined ICP (<20 mm Hg) and CPP (60-70 mm Hg) and PbO_2 (> 20 mm Hg) was superior to ICP and CPP therapy alone.[76-78] To increase a low PbO_2 (<20 mm Hg), mechanical ventilator settings should be optimized. A challenge of 100% oxygen for 2 minutes (a temporary method to restore PbO_2 and to verify probe function) can be performed and CPP and ICP, hemoglobin, and sedation should be optimized.[79]

Near-Infrared Spectroscopy

Pulse oximetry for the brain relies on the principle of reflectance spectroscopy in which near-infrared light traverses bone. The light is scattered and reflected in a ratio that is inversely proportional to the concentration of light-absorbing materials in tissue (e.g., hemoglobin and oxyhemoglobin). The surface detector is constructed and calibrated to detect light that has traversed down to the cerebral cortex and back. An adjacent detector is positioned to detect a signal from superficial tissues, and both signals are then used in an algorithm to derive an estimated tissue saturation.[80]

NIRS is a noninvasive approach to continuously monitor a regional critical oxygen supply/demand mismatch. The normal range lies between 60% and 75%, but the lower threshold varies considerably among individual patients.[81] Unfortunately, the sensitivity to detect isolated cerebral hypoperfusion is low, and, therefore, high-quality data supporting the use of NIRS in patients with TBI, SAH, or stroke are missing.[36,66] In contrast, NIRS is an excellent trend monitor in patients with cerebral hypoperfusion caused by systemic changes, such as during cardiac surgery where a decreased NIRS compared to the awake baseline correlates with a poor outcome.[81-83]

BRAIN METABOLISM AND BIOCHEMISTRY—CEREBRAL MICRODIALYSIS

Cerebral microdialysis probes can assess the biochemical milieu of the brain. The probes are placed through a burr hole and cycle small volumes of dialysate through the catheter to an extracranial collection system. The tip of the catheter should be placed in at-risk brain tissue, which is most vulnerable to secondary brain damage.[84] A semipermeable membrane (molecular weight cutoff of 20 kDa) is incorporated in the tips of the probes through which various substances can diffuse along their concentration gradient (e.g., lactate, pyruvate, glucose, glycerol, and glutamate) into the dialysate for collection and analysis using a bedside high-pressure liquid chromatography device.[85] As these substances are associated with glucose metabolism, hypoxia/ischemia, and cellular energy failure, the cerebral microdialysis is used to guide individualized intensive care therapy to optimize substrate supply, cerebral perfusion, and oxygen transport.[86] An increased lactate:pyruvate ratio with a low pyruvate concentration in combination with a low-glucose concentration can indicate a profound reduction in energy substrate supply and is associated with poor outcome after brain injury.[87] In contrast, an increased lactate:pyruvate ratio with normal pyruvate and glucose concentrations is an indicator of a nonischemic cause (e.g., mitochondrial dysfunction).[88] Glutamate is a marker of excitotoxic brain damage and glycerol can indicate membrane breakdown of neurons.[89,90] Recently, probes with a high-molecular-weight cutoff membrane (100 kDa) have been used to detect biomarkers for neuronal damage like S100B or cytokines.[91,92] Despite promising results, the clinical utility of a therapy guided by cerebral microdialysis is still under discussion.

NEUROPHYSIOLOGIC MONITORING

Clinical neurophysiology picks up the electrical activity of the central or peripheral nervous system.[93] It includes electroencephalography (EEG), evoked potentials (EP), and electroneuromyography and is very useful for diagnosis, prognosis, and follow-up of cerebral disorders.[93] However, clinical neurophysiology only evaluates the current functional brain status and cannot predict future complications.

Electroencephalography

The electroencephalogram (EEG) records spontaneous electrical activity of cortical neurons detected by appropriately placed electrodes in a radial and axial array as defined by the 10/20 system, an internationally standardized system of recording. The EEG is a surrogate parameter for functional metabolism of the cortical neurons and the integrity of the brain. The spectrum of component frequencies, together with amplitude and power, can be quantified and analyzed in a variety of fashions, and processed EEG monitors use these to assess the depth of anesthesia. In unconscious patients in the neurocritical care unit, EEG should be continuously used for the detection of nonconvulsive seizures, which can frequently occur and are associated with intracranial hypertension and cerebral metabolic derangements.[94,95] As the detection of nonconvulsive seizures is difficult, automatic monitoring systems have been developed.[96] Unfortunately, the current automatic detection of seizures is fraught with false negatives and false positives and cannot replace an EEG-trained neurologist.[96]

For prognosis after anoxic brain damage, poor outcome is associated with malignant EEG patterns like burst-suppression, α-coma, and low-voltage delta. In contrast, the persistence of EEG reactivity is an indicator of good outcome. Further development of intracranial electrocorticography, an invasive form of EEG monitoring, might allow the continuous detection of so-called spreading depolarizations, which occur in about half the patients with head trauma and can lead to secondary brain damage.[97,98]

Evoked Potentials

EPs measure changes in neuronal activity, which are triggered by sensory stimuli.[93] They reflect the passive response of the cerebral cortex or the brainstem to peripheral (acoustic, somatosensory, or visual) or central (transcranial magnetic stimulation) stimuli. In contrast to the EEG, where spontaneous cortical activity is recorded, the EPs monitor the integrity of central and peripheral tracts. The EP signals are quantified according to latency and amplitude. In the absence of peripheral or cervical dysfunction, the bilateral absence of the N_20 somatosensory EP response to median-nerve stimulation is the most reliable predictor of non-awakening in post-anoxic coma, whereas the preservation of cognitive evoked potentials (CEP) predicts awakening with a very high probability, irrespective of coma etiology.[93,99] After TBI, impairment of brainstem activity is the best predictor of bad outcome.[93]

MULTIMODALITY NEUROMONITORING

Multimodality monitoring uses a combination of parameters to identify, prevent, and treat the mechanisms of secondary brain damage and guide individualized therapy.[61,100] Various commercial systems are available to process and display multiple data streams.[101] The combination of ICP, cerebrovascular autoregulation, PbO_2, continuous EEG, and cerebral microdialysis offers the possibility to individualize care decisions in patients with severe brain injury.[39] In the future, the development of computational model interpretation of these complex multimodal data sets will provide summary outputs of patient-specific simulations of brain state to facilitate the interpretation and suggest individual therapies.[36,102]

RADIOGRAPHIC IMAGING

The most important diagnostic modalities for unconscious and brain-injured patients are CT, including

TABLE 84.6 Marshall Scale: Computed Tomography Categories for Head Injury

Category	Definition
Diffuse injury I	No visible intracranial pathologic process
Diffuse injury II	Cisterns are present with midline shift of 0-5 mm and/or lesion densities present; no high- or mixed-density lesions at >25 mL
Diffuse injury III	Cisterns compressed or absent, with midline shift of 0-5 mm; no high- or mixed-density lesions of >25 mL
Diffuse injury IV	Midline shift of >5 mm; no high- or mixed-density lesion of >25 mL
Evacuated mass lesion (V)	Any lesion surgically evacuated
Nonevacuated mass lesion (VI)	High- or mixed-density lesion of >25 mL; not surgically evacuated

TABLE 84.7 Classification of the Severity of Traumatic Brain Injury

Criteria	Mild	Moderate	Severe
Structural imaging	Normal	Normal or abnormal	Normal or abnormal
Loss of consciousness	< 30 min	30 min to 24 h	>24 h
Posttraumatic amnesia	0-1 day	>1 and <7 days	>7 days
GCS (best available in 24 h)	13-15	9-12	3-8
Abbreviated injury scale score: Head	1-2	3	4-6

GCS, Glasgow Coma Scale.

CT-angiography, and magnetic resonance imaging (MRI). CT and CT-angiography are very efficient methods, while MRI is time consuming but more sensitive for brainstem lesions as well as for axonal injuries. These imaging techniques are used to diagnose damage after TBI (intracranial masses, cortical contusions, and neuronal/axonal injury), an epidural or subdural hematoma, subarachnoid hemorrhage (SAH), ischemic or hemorrhagic stroke, cerebral vein/sinus thrombosis, or postoperative complications such as brain edema or rebleeding.

It is important to standardize and categorize CT images for meaningful comparison of therapeutic modalities in clinical trials and for assessment of prognosis. For TBI, the novel Stockholm and Helsinki CT scores seem to give a more accurate outcome prediction compared to the Marshall CT classification and the Rotterdam CT score (Tables 84.6 and 84.7).[103] After SAH, the Hijdra sum score seems to be superior to the more commonly used modified Fisher scale in assessing the amount of subarachnoid blood and in predicting the occurrence and severity of cerebral vasospasm.[104,105] (Tables 84.8 and 84.9). For early assessment of neuronal damage after stroke, the Alberta Stroke Program Early CT Score (ASPECTS) uses signs of early ischemic lesions in regions M1 to M6 and the basal ganglia.[106,107]

TABLE 84.8 Fisher Scale (Computed Tomography Appearance)

Grade	Clinical Presentation
Grade 1	No blood detected
Grade 2	Diffuse deposition of subarachnoid blood, no clots, and no layers of blood <1 mm
Grade 3	Localized clots and/or vertical layers of blood ≥1 mm in thickness
Grade 4	Diffuse or no subarachnoid blood, but intracerebral or intraventricular clots present

TABLE 84.9 Modified Fisher Scale (Computed Tomography Appearance)

Grade	Clinical Presentation
Grade 0	No blood detected
Grade 1	Thin subarachnoid blood*, no intraventricular hemorrhage
Grade 2	Thin subarachnoid blood, with intraventricular hemorrhage
Grade 3	Thick subarachnoid blood, no intraventricular hemorrhage
Grade 4	Thick subarachnoid blood, with intraventricular hemorrhage

*Vertical thickness of 1 mm separates thin from thick subarachnoid hemorrhage.

Common Diseases in the Neurocritical Care Unit

TRAUMATIC BRAIN INJURY

Severe TBI is mainly a result of traffic accidents, assaults, falls, and domestic abuse. It is the leading cause of disability and death in young male adults.[108,109] Poor outcomes after TBI are correlated to older age and are worse after falls.[110,111] The primary injury, which is defined by the kinetic impact of the trauma, deforms the brain structure. The pattern of this damage covers a wide spectrum from localized contusion to diffusely scattered foci, lacerations, and hematomas varying with the circumstances of the incident and the architecture of the victim's brain. TBI is classified by whether it is via blunt or penetrating mechanism. Penetrating injury may again have widely varying consequences depending on site, depth, and energy, but is generally fatal if it bilaterally traverses the midbrain.[112] The GCS categorizes TBI into mild, moderate, and severe injury according to the patient's presenting clinical characteristics and correlates with outcome after TBI (see Table 84.2).[113] Additionally, the Abbreviated Injury Scale (AIS) score for the head and neck region classifies TBI by ranking injuries on a six-point scale based on mortality risk, with "1" indicating minor injury and "6" indicating a nonsurvivable injury. Both scores are comparable in predicting short-term mortality after severe TBI.[114]

The management of TBI in the ICU should include comprehensive examination and assessment using such principles as outlined in the Advanced Trauma and Life Support protocol because occult injuries can escape initial screening.

Pathophysiology

As the brain has no tolerance for hypoxia, TBI patients need immediate treatment according to current guidelines.[24] Unfortunately, the extent of the primary injury cannot be influenced by therapy and, therefore, prevention (e.g., by helmets or airbags) is the only way to avoid damage. The primary brain damage triggers a cascade of pathophysiologic changes, which then lead to secondary brain damage. During the first post-traumatic days, the aim of treatment is to minimize the growth of the secondary damage as much as possible in order to rescue salvageable brain tissue. Pathologic processes such as elevated ICP (due to edema, hemorrhage, obstruction of CSF flow), diminution of arterial inflow, and consequent reduction in CPP with resulting tissue hypoxia and loss of cerebrovascular autoregulation increase secondary brain damage. Inflammation, massive release of excitatory neurotransmitters, apoptotic cell death, high lactic acid concentrations due to anaerobic glycolysis, depleted adenosine triphosphate (ATP)-stores, increased intracellular Ca^{2+} concentrations, generation of free radicals and proteolysis are some of the identified contributors to secondary brain damage. Unfortunately, despite intense research and characterization of all these mechanisms, no drug has been identified that can improve outcome after TBI in randomized, prospective clinical trials. This is most likely related to the complex pathophysiology of brain damage, the heterogeneous patterns of damage, and various preexisting patient diseases. TBI also leads to disturbances in other systems such as: sympathetic discharge of the autonomic nervous system, inflammatory responses, endocrine dysfunctions, electrolyte imbalances, cardiovascular and respiratory disturbances, and coagulation impairments. These systemic effects must be monitored and immediately treated, as they also contribute to secondary brain damage.

Traumatic SAH (tSAH) occurs in up to 60% of admissions for TBI and influences outcome after TBI.[115-117] Approximately 20% of patients with tSAH may also develop vasospasm, which causes secondary ischemic insult.

Treatment

All therapeutic strategies focus on optimization of the delivery of oxygen and glucose to the brain cells. These strategies include maintaining adequate CPP, controlling ICP, and optimizing oxygenation. Therefore, in the critical care setting, the management of TBI patients should follow established protocols with close monitoring of parameters, including CPP, ICP, and oxygenation status.[118] Clinical assessments like continuous measurement of arterial blood pressure, heart rate, and pulse oximetry in combination with monitoring volume status, urine output, and GCS have to be performed.

Cerebral Perfusion Pressure. CPP results from the difference of MAP minus ICP and should be kept between 60 and 70 mm Hg.[24] Aggressive attempts to maintain CPP above 70 mm Hg with fluids and vasopressors should be avoided, as this treatment increases the risk of respiratory failure. Arterial hypotension with a SBP below 90 mm Hg is strongly correlated to poor outcome and has to be avoided in the management of TBI patients.[14,116] There exists a smooth U-shaped relationship between systolic or MAP and outcome without any evidence of an abrupt threshold effect. Therefore, while current recommendations are to maintain SBP above 100 mm Hg for patients 50 to 69 years old or at or above 110 mm Hg for patients 15 to 49 or over 70 years old, new data possibly suggest that an optimal SBP of 135 mm Hg should be the target.[24,119]

BOX 84.2 Management Checklist for the Treatment of Intracranial Hypertension

1. Keep physiological variables in normal range (normotension, normocapnia, normoxia, normothermia, normoglycemia, normovolemia)
2. Head position (30-degree elevation); avoid rotation of the head
3. CPP 60-70 mm Hg; massive fluid-therapy or high doses of vasoconstrictors should be avoided
4. Normocapnia ($PaCO_2$ = 35-40 mm Hg); if ICP >20-25 mm Hg, then induce short-term hyperventilation ($PaCO_2$ = 30-35 mm Hg)
5. Provide adequate sedation
6. CSF drainage if ventricles are still detectable
7. Consider mannitol or hypertonic saline
8. Consider barbiturate therapy (under EEG monitoring)
9. Fever control

CPP, Cerebral perfusion pressure; *CSF*, cerebral spinal fluid; *EEG*, electroencephalogram; *ICP*, increases intracranial pressure; *$PaCO_2$*, arterial partial pressure of carbon dioxide.

Intracranial Pressure. Elevated ICP above 22 mm Hg is associated with increased mortality and should be treated[24] with measures according to the checklist in Box 84.2. This includes optimizing patient position, osmotherapy, deep sedation with barbiturates or propofol, and ventricular drains.[120] Hyperventilation reduces CBV and ICP due to its vasoconstrictive effect, but at the same time hyperventilation leads to a mismatch between oxygen delivery and oxygen consumption.[121] Therefore, hyperventilation is only a temporizing measure until other ICP-lowering measures are available. Decompressive craniectomy has been a strategy to lower ICP, but unfortunately this intervention increases the number of patients surviving in a vegetative state or with severe brain damage.[122,123] Prophylactic mild hypothermia was also a promising intervention to reduce ICP; however, in prospective multicenter studies, this therapy was not superior to normothermia.[35] ICP control with high-dose steroids was shown to have an adverse effect on mortality and morbidity in a multicenter study of more than 10,000 patients with brain injury.[124] Therefore, steroids are not recommended for control of ICP after TBI.

Oxygenation and Ventilation. Patients with GCS scores of 8 or less should be intubated and ventilated with a target of PaO_2 above 80 mm Hg. If PEEP is necessary, levels up to 15 cm H_2O have been shown to increase brain tissue oxygen pressure and oxygen saturation without increase in ICP or decrease in CPP.[19]

Sedation. TBI patients should be sedated with drugs with a short context-sensitive half-life like propofol to facilitate daily examination of their neurologic condition. Care should be taken to screen patients for propofol infusion syndrome, which can occur when high-dose propofol is used over several days.[125] Most of the barbiturates and benzodiazepines have a longer half-life and are, therefore, less suitable. Low-dose inhalational anesthetic can also be used. At higher concentrations, volatile anesthetics possess a direct vasodilatory effect, which increases CBV and, in turn, ICP. Ketamine was contraindicated in TBI patients due to perceived risks of causing intracranial hypertension, but in intubated and ventilated patients, ketamine has no adverse effect on ICP.[126] Ketamine has several favorable effects like reduced need of supplementary vasopressors and narcotics, activation of bowel movement, and bronchodilation.[127] Narcotics, like sufentanil, fentanyl, and remifentanil, have no negative effects on ICP as long as MAP is maintained. Muscle relaxants can be used in TBI patients, with the potential exception of succinylcholine, which possibly increases ICP. Nitrous oxide (N_2O) and etomidate should not be used in patients after severe TBI.

Additional Interventions. In TBI patients, enteral nutrition is recommended to attain basal caloric replacement between the fifth and the seventh day after TBI.[24] Enteral feeding using a transgastric jejunal tube should be started as soon as possible.[128-130] Early tracheotomy can facilitate the weaning of the patients and reduce mechanical ventilation days, but there is no evidence that it reduces mortality or the rate of nosocomial pneumonia. Up to 25% of patients with isolated TBI develop deep vein thrombosis (DVT) with the risk of pulmonary embolism.[131] Low-molecular-weight heparin or low-dose unfractionated heparin should be used in combination with mechanical prophylaxis, despite the increased risk of intracranial hemorrhage expansion.[24] The Parkland Protocol, which stratifies patients into different risk groups for spontaneous progression of hemorrhage, can help assess the optimal timing for the start of DVT prophylaxis.[132] The incidence of early posttraumatic seizures (during the first week after TBI) can be reduced by phenytoin.[24] As these early posttraumatic seizures do not influence outcome, this prevention is not obligatory. Late posttraumatic seizures are not susceptible to prophylactic interventions.

SPINAL CORD INJURY

In up to 5% of all major trauma cases, the spinal cord is injured and about 14% of these patients suffer from an unstable spine injury.[133] The American Spinal Injury Association (ASIA) has classified SCI into five categories, where ASIA A represents a complete impairment and ASIA E represents normal sensation and motor function (Table 84.10). Surgical decompression of the spinal cord should be performed within 24 hours after SCI and is associated with improved neurologic outcome.[134,135]

TABLE 84.10 ASIA Classification of Spinal Injury

Grade	Clinical Presentation
Grade A	Complete. No sensory or motor function is preserved in the sacral segments S4-S5
Grade B	Incomplete. Sensory but not motor function is preserved below the neurological level and includes the sacral segments S4-S5
Grade C	Incomplete. Motor function is preserved below the neurological level, and more than half of key muscles below the neurological level have a muscle grade less than 3 (Grades 0-2).
Grade D	Incomplete. Motor function is preserved below the neurological level, and at least half of key muscles below the neurological level have a muscle grade greater than or equal to 3
Grade E	Normal. Sensory and motor functions are normal.

Damage to the sympathetic outflow to the heart and vasculature after SCI contributes to systemic hypotension and bradycardia due to unopposed vagal tone, commonly referred to as neurogenic shock.[136] Injuries above T7 have an 85% risk of serious cardiovascular instability.[137] To avoid secondary injury after SCI, the MAP should be kept above 85 to 90 mm Hg during the first 7 days after injury using fluid and vasopressor therapy.[138,139] Fluid therapy should be monitored by cardiac output monitoring devices and hypotonic solutions like dextrose 5% in water, Ringer´s lactate, and 0.45% sodium chloride should be avoided, as they worsen cord edema. Vasopressors should be inotropic, chronotropic, and vasoconstrictive like α_1- and β_1-agonists (dopamine, norepinephrine). Dobutamine has generally no indication because of its β_2-receptor activation and its vasodilatory effects. In cases with life-threatening bradycardia, a cardiac pacemaker placement can be considered.[140]

The need for ventilatory support depends on the level of injury. The muscles contributing to respiration are the diaphragm (phrenic nerve, C 3-5), the intercostal muscles (thoracic nerves), and the accessory muscles, including the sternocleidomastoid (cranial nerve 11) and scalene muscles (cervical plexus). Respiratory failure secondary to abdominal and intercostal muscle paralysis can still occur even with injuries below C5 because these muscles significantly increase the efficiency of diaphragmatic contractions. The traumatic sympathectomy also leads to intestinal atony with subsequent abdominal distention, which further deteriorates the efficacy of the already compromised diaphragm. With complete cervical SCI, acute respiratory failure is common, secondary to the sudden loss of functional residual capacity and the inability of the sternocleidomastoid muscle to stabilize the chest wall. As hypoxia leads to poor outcome after SCI, patients who develop respiratory insufficiency should be intubated as soon as possible. Weaning should be started early and if it is complicated, the patient should receive a tracheostomy to reduce mechanical ventilation days, decrease the need for sedation, and facilitate pulmonary toilet.

Lower limb blood flow is reduced with increased arterial and venous pooling. This is associated with a higher incidence of thromboembolic disease, and early administration of venous thromboembolism prophylaxis within 72 hours after injury is recommended. Inferior vena cava filters are not suitable for prophylaxis.[138]

Many drugs have been tested for their potential neuroprotective effects; however, high-dose methylprednisolone, monosialotetrahexosylganglioside (GM-1), riluzole, fibroblast growth factor, minocycline, or magnesium have not improved outcome after SCI in prospective, randomized, multicenter studies.[141] Early mild hypothermia after SCI showed some promising results in clinical studies; however, they have to be validated by prospective, randomized, multicenter studies.[142]

Cerebrovascular Disease

Cerebrovascular diseases are the leading cause of death and disability worldwide.[143] Although clinical presentations and outcomes are highly variable, initial management often requires critical care resuscitation. Ischemic strokes are the most common (80%-90%) of stroke subtypes and are increasingly a larger proportion of post-procedural ICU management. Hemorrhagic strokes account for the remaining 10% to 20% of strokes, but are often the most medically complex and have the longest length of stay and highest morbidity and mortality in the ICU.[144] The following sections will provide an overview of the most common critical care management issues for SAH, ischemic stroke, and intracerebral hemorrhage (ICH).

SUBARACHNOID HEMORRHAGE

SAH is a neurologic emergency that requires critical care management. Accounting for less than 5% of all strokes worldwide, SAH is associated with severe morbidity and mortality. Most cases of SAH are aneurysmal in origin (aSAH). The incidence of aSAH per 100,000 person years is variable by ethnicity and geography—the lowest incidence being in China (2), followed by Central and South America (4.2), United States (8-15), and the highest being in Finland and Japan (19-23).[145,146] Women have a greater risk than men by a factor of 1.24, with a higher incidence among blacks and Hispanics compared to Caucasians. Most aneurysms occur between ages 40 and 60 years, with a mean age of 55 years.[145] Risk factors for aSAH include cigarette smoking, hypertension, heavy alcohol abuse, use of sympathomimetic agents, family history of SAH, and prior history of aSAH.[147] Between 10% and 15% of patients will die before hospitalization, and 25% will die within the first 48 hours. The initial hemorrhage is usually the primary cause of death, followed by rebleeding.[148] Case fatality rates had continued to decline in recent decades from 50% to 33% with the advent of endovascular treatment, microsurgical techniques, and improved ICU management.[149]

Early Brain Injury

The degree of neurologic abnormalities and the amount of bleeding are the strongest predictors of clinical outcome and complications after SAH. The Hunt and Hess grading system and World Federation of Neurological Surgeons Scale (WFNSS) are the most widely used (see Tables 84.3 and 84.4) with higher WFNSS and Hunt and Hess grades associated with worse clinical outcomes.[41,42] In the first 72 hours after the acute bleed, multiple mechanisms such as transient global ischemia, elevated intracranial pressures, and toxicity from SAH have been implicated in early brain injury. Subsequent effects on CBF, microcirculatory changes, cerebral edema, and sympathetic response can lead to both neurologic and systemic complications.[150,151] Acute management of blood pressure and oxygenation are critical in this period along with the prevention of early complications such as rebleeding, acute hydrocephalus, and elevated ICPs. Ideally, patients should be managed in high-volume facilities with dedicated neurocritical care units.[152]

Rebleeding. Rebleeding is a serious complication that significantly worsens outcomes and increases mortality as high as 70%.[153] The risk of rebleeding is the highest within the first 24 hours (4%-15%) after the initial bleed, remains elevated for the next 2 to 4 weeks (1%-2% per day), then eventually decreases to 2% to 4% annually after the first 6 months.[154-156] To reduce the risk of rebleeding, guidelines recommend securing the ruptured aneurysm by surgical clipping or endovascular coiling as soon as possible and ideally within the first 24 hours after symptom onset.[157-159] Since the publication of the International Subarachnoid Aneurysm Trial, endovascular coiling is the recommended treatment when the location, size, and morphology of aneurysm are favorable. Some aneurysms may be more suitable for surgical clipping. There should not be any delay in securing a ruptured aneurysm, regardless of the treatment modality chosen.[160,161] When surgical clipping or endovascular coiling are delayed, short-term (less than 72 hours) treatment with antifibrinolytic agents (aminocaproic acid or tranexamic acid) is recommended. In addition, seizure prophylaxis can be considered until the aneurysm is treated along with blood pressure control to normotensive goals.[158,162,163]

Acute Hydrocephalus. Acute hydrocephalus develops in 25% to 30% of patients after SAH, and emergency ventriculostomy may be lifesaving.[164] Patients with hydrocephalus can develop progressive deterioration leading to stupor and coma as well as more subtle clinical signs of gaze palsy, pupillary dysfunction, and cognitive slowing. Head CT showing ventricular dilation can be diagnostic and can facilitate early ventriculostomy placement. Hydrocephalus after SAH can be caused by obstruction of CSF outflow by blood products or by impaired CSF absorption by arachnoid granulations.[165] Most patients should have ventriculostomy drains removed when they no longer require external drainage and ICPs have stabilized. Some patients will develop delayed hydrocephalus (3-21 days after the onset), and 20% of patients will need ventriculoperitoneal (VP) shunt placement for chronic hydrocephalus.[157]

Neurogenic Cardiac and Pulmonary Disturbances. Cardiac and pulmonary disturbances are common after SAH and are thought to be secondary to a surge in catecholamine levels and sympathetic tone.[166,167] Significant autonomic nervous system disturbance after SAH can result in changes in the electrocardiogram and lead to myocardial dysfunction. Transient ECG abnormalities range from sinus tachycardia, peaked T-waves, T-wave inversions, and QT prolongation to ST segment depression or elevation.[168] Electrocardiographic changes are frequent but do not appear to relate to outcome.[169]

Cardiac dysfunction, however, can have a significant impact on management after SAH. Abnormal echocardiography has been described in up to 8% of SAH patients. Poor grade SAH patients can develop sudden hypoxemia and cardiogenic shock with or without pulmonary edema. This phenomenon of neurogenic stunned myocardium can cause severe limitation of cardiac contractility, which is reversible and associated with a good recovery profile. Patients with SAH have echocardiogram changes similar to takotsubo cardiomyopathy, which is also an acute transient dysfunction resulting from sympathetic overactivity.[170] Adrenoreceptor polymorphism has been implicated

BOX 84.3 Suggested Cardiovascular Management Strategies in Subarachnoid Hemorrhage

General

1. Manage hypertension in unsecured aneurysms (systolic BP < 140 mm Hg)
2. Maintain euvolemia prophylactically; no role for prophylactic hypervolemia.
3. Administer nimodipine.

Cardiovascular Instability

1. BP and cardiac output goals will alter as aneurysm is secured.
2. ECG

If abnormal (QTc prolongation, ST-segment changes): check troponins.

If troponins elevated: perform echocardiography.

3. Perform echocardiography if any hemodynamic lability or heart failure is suspected.
4. Monitor cardiac output.
5. Select vasopressors for cardiac output and blood pressure.
6. Consider aneurysm treatment as soon as practical.
7. Reserve coronary catheterization for isolated wall motion deficit and rising troponins (coil aneurysm first if possible).
8. Delayed cerebral ischemia: treat with euvolemia/mild hypervolemia, vasopressors, and cardiac output monitoring; adjust management based on perfusion targets when possible.
9. Transfusion: maintain hematocrit >25%.

BP, Blood pressure; *ECG,* electrocardiogram.

in myocardial stunning. Different receptor genotypes have an increased sensitivity to catecholamines and are associated with a 3- to 4.8-fold increased risk of cardiac injury and dysfunction.[171]

Troponins are frequently elevated in about 30% of patients after acute SAH. High serum levels are associated with increased hemorrhage, hemodynamic fluctuations, and worse outcomes.[172] Release of troponin can represent cardiac ischemia in patients with atherosclerotic heart disease or a "myocardial leak" from neurogenic injury.[172]

Cardiac dysfunction may complicate and limit the active treatment options for delayed cerebral ischemia (DCI) and increased ICP. A typical strategy for cardiovascular management is given in Box 84.3 based on comprehensive consensus guidelines.[157,158]

Pulmonary injury is a frequent complication after SAH, with nearly 17% of patients developing severe pulmonary dysfunction, including ARDS, which is associated with poor neurologic outcome.[173] In addition to acquired respiratory infections, common in ventilated ICU patients, neurogenic pulmonary edema caused by increased permeability of the pulmonary vasculature can occur in isolation or in combination with neurogenic cardiac problems.[174]

Secondary Brain Injury

Delayed Cerebral Ischemia. DCI is one of the most severe complications of SAH and is associated with worse outcomes. Although the exact mechanism of DCI is still unclear, multiple potential causes beyond cerebral vasospasm have been investigated, including microcirculatory dysfunction, microthrombosis, cortical spreading depolarization, and neuroinflammation.[175,176] About one-third of patients will develop symptoms from DCI as early as 3 to 5 days after the onset, with a peak frequency between 5 and 7 days, generally waning over 2 to 4 weeks. Seventy percent of patients will develop angiographic vasospasm, although only 30% to 40% of patients will become symptomatic. In addition, not all patients with DCI have evidence of vasospasm, suggesting vasospasm-independent mechanisms.[177]

Cerebral vasospasm is still considered as a cause of DCI, and most often the target of treatment interventions. Patients with a large amount of subarachnoid blood are at a higher risk for developing vasospasm. Radiographic tools such as the Hijdra sum score and Fisher score were developed to predict vasospasm (Table 84.8).[104,178] The modified Fisher score is the most commonly used to clinically prognosticate the risk of vasospasm (Table 84.9),[179] with the highest incidence of vasospasm observed in patients with modified Fisher grade 4.[180] Vasospasm monitoring is facilitated by serial clinical exams and the use of imaging modalities such as transcranial Doppler, CT with perfusion, and cerebral angiography.

Medical management of DCI centers on augmentation of arterial blood pressure with vasopressors, in the context of euvolemia rather than hypervolemia.[181] "Triple-H therapy," hypertension-hypervolemia-hemodilution, is no longer recommended because there was little evidence of benefit and potential harm shown in randomized control trials and meta-analyses.[182] The use of deliberate transfusion to increase oxygen delivery in the setting of DCI is controversial and needs to be balanced against the deleterious effects of transfusion. A prospective trial is awaited. Trials of endothelin antagonists and statins provided further evidence of some dissociation between vasospasm and clinical outcomes, as neither drug class showed any effect on outcome despite a decrease in the incidence of vasospasm.[183]

Nimodipine should be started for all patients as soon as possible after diagnosis for 21 days. Studies on the use of nimodipine provide the only level I evidence from randomized control trials in SAH that showed modest reduction in the incidence of ischemic deficit without any apparent effect on angiographic vasospasm.[184-187]

In patients who are refractory to medical therapy for DCI, the use of endovascular therapies can be considered.[188,189] Mechanical balloon dilation of blood vessels (angioplasty) can provide an effective treatment for vasospasm involving the larger arteries.[190,191] Intraarterial injection of vasodilator agents, most commonly calcium channel blockers such as nicardipine and verapamil, can be effective in smaller caliber vessels but are limited by the transient nature of their effects (<24 hours).[192]

Hyponatremia. Hyponatremia is observed in 30% to 40% of patients with SAH, and is most commonly the result of cerebral salt-wasting syndrome (CSWS) or the syndrome of inappropriate secretion of antidiuretic hormone (SIADH).[193] Because these two conditions have different pathophysiology, correct diagnosis and management of hyponatremia is important, particularly when it precedes development of DCI and can worsen clinical outcome. In CSWS, sodium is actively excreted from the body in high concentration, and accompanying diuresis occurs, despite ongoing hyponatremia with hypovolemia.[194] Management of CSWS is the replacement of sodium with isotonic or hypertonic saline to restore volume depletion. Fludrocortisone is considered if diuresis is active and precludes the

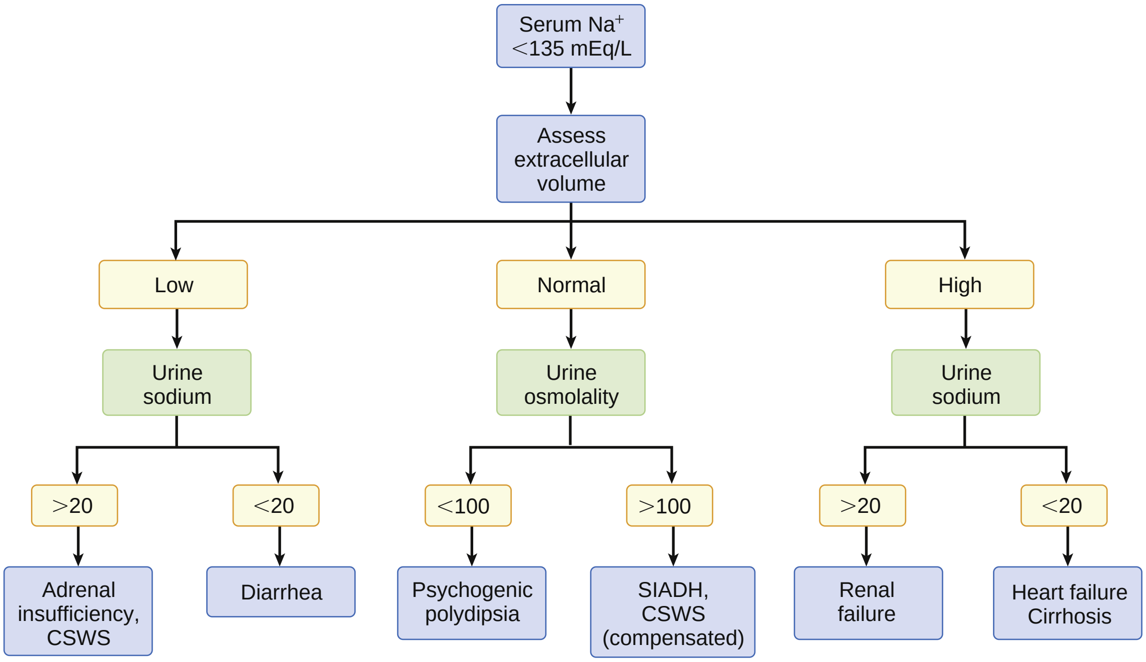

Fig. 84.7 Algorithm for the differential diagnosis of hyponatremia in the neurosurgical patient. *CSWS,* Cerebral salt-wasting syndrome; *SIADH,* syndrome of inappropriate secretion of antidiuretic hormone.

maintenance of adequate fluid balance.[157,158] Patients with SIADH are typically hypervolemic and are treated with fluid restriction to restore euvolemia and suppress antidiuretic hormone (ADH) release.[195] A suggested algorithm for resolving diagnostic uncertainty is given in Fig. 84.7.

ISCHEMIC STROKE

Stroke is the fifth leading cause of death in the United States and the second leading cause of death globally, accounting for nearly 12% of deaths worldwide with disproportionately higher mortality rates in lower income countries. Although mortality has declined in the United States, stroke remains a major source of disability.[196,197]

Acute ischemic stroke (AIS) is increasingly a treatable neurologic emergency. The deprivation of oxygen and nutrients to the brain beyond the combined thresholds of severity and time induces cellular death in neuronal tissue, resulting in ischemic infarction. The ischemic penumbra is potentially salvageable when factors such as collateral flow and residual perfusion blood flow to brain tissue yield a longer period before irreversible ischemic injury, thereby giving the opportunity for aggressive intervention with revascularization therapies such as thrombolysis and mechanical thrombectomy. Current guidelines recommend intravenous thrombolytics within 4.5 hours and embolectomy with modern thrombectomy devices for large vessel occlusion within 6 hours of symptom onset in eligible patients.[198-200] With current perfusion imaging tools, embolectomy in expanded time windows after stroke onset has shown efficacy in selected patients.[201] Vertebrobasilar occlusion may also benefit from the more recent techniques in even longer time windows.[202]

Successful management of AIS extends beyond the emergency treatment to reperfuse and recover threatened brain tissue. Ongoing management in the critical care setting is necessary to maintain adequate CBF to protect the ischemic penumbra and address factors that adversely affect vulnerable ischemic brain tissue such as fever and abnormal glucose. Early management of the potential complications of AIS, including postinfarction cerebral edema, hemorrhagic transformation, and reperfusion injury, are critical to improving patient outcomes.

Hypotension is uncommon after AIS but requires aggressive management. Neurologic deterioration, poor outcomes, and increased mortality have been reported with baseline blood pressures less than 100/70 mm Hg.[203] Common causes of arterial hypotension include hypovolemia, blood loss, decreased cardiac output, myocardial infarction, and arrhythmias. Neurocardiogenic injury has been described in particular with involvement of the right insula and may predispose to ECG changes and life-threatening arrhythmias.[204,205] The most common arrhythmia associated with AIS is atrial fibrillation.[206] Cardiac monitoring is recommended for at least the first 24 hours after stroke, with additional monitoring of cardiac function if there is evidence of symptomatic heart failure.

Elevated blood pressure should not be aggressively treated in the acute setting because the potential risk of lowering blood pressure may threaten penumbral perfusion and exacerbate brain ischemia. Urgent antihypertensive treatment may be needed for medical complications such as hypertensive encephalopathy, aortic dissection, and acute organ failure. Cautious lowering of blood pressure by 15% if it exceeds 220/120 mm Hg is indicated in certain clinical conditions. Because of the risk of hemorrhagic transformation with thrombolysis, blood pressure should be lowered to less than or equal to 185/110 mm Hg prior to treatment and maintained at less than 180/105 mm Hg for at least 24 hours. Similar blood pressure goals are recommended after revascularization procedures such as intraarterial thrombolysis and embolectomy.[198]

Hypoxia can also exacerbate ischemic injury. Poor airway control, hypoventilation, and aspiration pneumonia are most common after AIS. The patient's airway should be assessed, and tracheal intubation must be considered in stuporous or comatose patients. In addition, patients with brainstem involvement may be at high risk for aspiration. Although intubation and mechanical ventilation is associated with poor outcome and increased mortality, prevention of hypoxia and aspiration pneumonia should be considered.[198]

Changes in the patient examination after AIS may indicate a hemorrhagic complication, cerebral hyperperfusion, or cerebral edema and should prompt an emergent noncontrast CT. Thrombolysis bleeding should be treated with emergency administration of cryoprecipitate. Other rare events to monitor after alteplase administration include allergic reactions such as anaphylaxis and angioedema.[207,208] Attention should be paid to any signs of systemic hemorrhage such as lower abdominal pain, which may indicate retroperitoneal bleeding after embolectomy. Cerebral hyperperfusion is rare, but can also cause neurologic symptoms likely caused by sudden, rapid increase in CBF following revascularization. If severe, patients may develop headache, seizures, confusion, and potentially fatal cerebral edema and intracranial hemorrhage. Blood pressure should be monitored and lowered in patients with suspected hyperperfusion syndrome.[209]

Cerebral edema typically occurs during the first 3 to 5 days after AIS and subsides by 2 weeks. The overall risk of significant cerebral edema is low but tends to occur with distal carotid artery or MCA occlusion with complete MCA infarction. A subset of patients can have early (within 24 hours) malignant cerebral edema with brain herniation signs, which is associated with the highest mortality after AIS. Posterior fossa strokes are also associated with rapid neurologic deterioration from brain edema. Cerebellar infarctions may produce local edema that causes acute hydrocephalus with brainstem compression that can lead to rapid coma and sudden respiratory failure. Medical management using hyperosmolar therapies with mannitol and hypertonic saline and temporary hyperventilation may be helpful. Surgical interventions include management of hydrocephalus with external ventricular drainage and decompressive craniectomy. Early suboccipital craniectomy is potentially lifesaving with good clinical results.[210] Hemicraniectomy for anterior circulation stroke remains more controversial. In selected patients when performed early, outcomes may be better. Based on the combination of randomized trials in Europe, early decompressive hemicraniectomy is effective in decreasing mortality and improving clinical outcome in survivors.[211,212]

A standardized and systematic approach to stroke treatment provided by certified stroke centers has been shown to improve outcomes. Established protocols for all stroke patients including their ICU care have led to more uniform management of not only emergency delivery of care, but also supportive medical care such as glucose control, prevention of deep venous thrombosis, nutrition, and early rehabilitation.[213]

INTRACEREBRAL HEMORRHAGE

ICH has an overall incidence of 24.6 per 100,000 person years, with a high case fatality rate especially in low-income countries.[214,215] Nontraumatic ICH is often categorized as spontaneous or primary when associated with risk factors such as hypertension, tobacco, alcohol and substance use, antithrombotic medications, underlying coagulopathy, and amyloid angiopathy (especially in lobar hemorrhages). ICH may also arise from secondary causes such as ruptured aneurysm, ruptured vascular malformation, conversion from ischemic stroke, or tumor. This wide range of differential diagnoses can swiftly be refined by CT angiogram and assessment of pathophysiologic effect, with accompanying clinical signs aiding localization. Angiography may be required to further characterize any underlying vascular sources such as aneurysm, arteriovenous malformation, or dural fistula.

Management is important to avoid secondary insult by reducing the incidence of rebleeding, hypoxemia, hypercarbia, or cerebral edema. Initial care is directed toward the airway and circulation, with control of arterial blood pressure and early reversal of coagulopathy to decrease the risk of ICH volume expansion and rebleeding.[215,216] If the ICH is in the posterior fossa or midbrain, consideration should be given to the insertion of a ventriculostomy and early surgical decompression to reduce the risk of hydrocephalus and brainstem compression. Patients with lesions in these regions are prone to airway and respiratory problems and may need early tracheal intubation to protect their airway and prevent aspiration. The use of clinical severity scores such as NIH Stroke Scale and GCS with hourly neurologic assessments can detect early clinical deterioration prompting repeat imaging and aggressive management of cerebral edema or hematoma expansion. Medical management of volume status and sodium can be critical in patients with cerebral edema requiring hyperosmolar therapies.[216] The use of validated prognostic scores such as the ICH score for mortality and FUNC score for functional independence are additional tools that providers can use to communicate goals of care.[217,218]

Hypertension after ICH is common and associated with increased hematoma volumes and worse outcomes. Based on randomized controlled trials of aggressive blood pressure management, lowering SBP to a range of 120 to 140 mm Hg was safe, but did not improve outcomes when compared to lowering SBP to 140 to 160 mm Hg and is reflected in the American Heart Association guidelines.[215,219-221] If the initial CT or MRI appearance suggests aneurysm or arteriovenous malformation, then care should be taken to limit blood pressure to reduce the risk of rebleeding. The addition of ICP monitoring allows setting a CPP target and provides a more physiologic approach to the management of systemic blood pressure.

Coagulopathy increases the severity of ICH, with significant hematoma expansion. Acute management with rapid reversal of coagulopathy is warranted.[222] In the setting of vitamin K antagonists, use of prothrombin complex concentrates (PCCs) is advocated. In a prospective, randomized trial of PCC compared to fresh frozen plasma (FFP), PCCs had significantly faster international normalized ratio correction, decreased hematoma expansion, and decreased mortality.[223] There were no significant differences with thrombotic complications, and PCCs avoided the risk of volume overload and transfusion reactions associated with FFP. In patients with known recent thrombotic events, PCCs should be used with caution. With increasing use of the novel oral anticoagulants (NOACs), there is a rising need for rapid reversal agents for NOAC-associated ICH. Idarucizumab is a monoclonal antibody that can bind to dabigatran and rapidly correct coagulopathy in the setting of life-threatening bleed. Andexanet alfa was recently approved by the FDA for reversal of factor Xa inhibitors.[222] In ICH patients on antiplatelet therapy, the use of platelet transfusions to reduce the risk of hematoma expansion and improve outcomes are more controversial. In a prospective, randomized trial of platelet transfusion within 6 hours compared to standard medical therapy in a nonsurgical ICH population, there was no benefit to transfusion, and an increase in mortality and higher disability.[224] Platelet transfusion prior to surgical intervention has not been well studied.

Other neuroprotection strategies remain unproven. Unlike SAH, nimodipine does not have an established role in ICH. Corticosteroids are also not indicated. Statins may be beneficial in ICH when continued in current users. However, starting statins in acute ICH has not been proven beneficial. The role of long-term statin and increased risk of recurrent bleed is also controversial.[215,225] Newer agents such as the iron chelator, deferoxamine, are currently in clinical trials. Large trials of surgical hematoma evacuation have not shown benefit.[226] However, in patients with cerebellar hemorrhage and brainstem compression or in those showing acute neurologic deterioration or obstructive hydrocephalus, surgical evacuation may be indicated.[215] The use of thrombolytics in intraventricular hemorrhage was shown in a randomized, controlled trial to improve mortality, but not functional outcome.[227] There are several ongoing trials testing the benefit of decompressive surgery without hematoma evacuation, minimally invasive surgery, catheter-based hematoma aspiration with thrombolysis (phase 3 trial), and new endoscopic devices.

STATUS EPILEPTICUS

Status epilepticus is a medical and neurologic emergency that is associated with significant morbidity and mortality. Defined as continuous or rapid sequential seizure activity without recovery between attacks, or more strictly, continuous seizure lasting at least 30 minutes, this condition affects both children and adults with an estimated annual incidence of 12.6 per 100,000 worldwide.[228] Although all types of seizures may present status epilepticus, there are two main classifications: convulsive (typically generalized tonic-clonic activity) and nonconvulsive. In addition, psychogenic or nonepileptic seizures can mimic status epilepticus and present their own particular diagnostic challenges.[229] In comatose critically ill patients, obtain an EEG if there are no other explanations for the comatose state.

Seizure activity may arise from multiple etiologies, including any major insult affecting the cerebral cortex (e.g.,vascular, infectious, mechanical, metabolic, or toxic). Even mild insults may provoke status epilepticus if the seizure threshold is reduced by preexisting parenchymal disease or comorbidity (e.g., alcohol withdrawal). Given the previously outlined emphasis on the avoidance and termination of secondary insult to the brain, management of status epilepticus is focused on acute stabilization, rapid control of seizures, and timely identification and treatment of the underlying etiology. Management guidelines have been published that address the important phases of management.[230] Initial goals in the first 5 minutes of treatment include stabilization of the patient's airway, breathing, and circulation with rapid assessment of any neurologic disability. The subsequent treatment phases are focused on seizure termination and prevention of recurrence. Prompt treatment of seizure in the first 5 to 10 minutes should be instituted because a seizure lasting beyond 5 minutes is unlikely to stop spontaneously. Recommended agents include midazolam, lorazepam, and diazepam. If seizures persist, second phase treatments include loading doses of anticonvulsants such as fosphenytoin, valproic acid, levetiracetam, or phenobarbital (if other agents are not available). Ongoing seizures beyond 40 minutes involve third-phase therapies, which include repeating second-line agents or moving to anesthetic doses of thiopental, midazolam, pentobarbital, or propofol. This approach would likely require intubation and ventilation. Paralytic agents should be avoided for the long-term due to fear of masking ongoing or recurrent seizures. Continuous EEG is highly recommended. In patients refractory to treatment, alternative options such as inhaled anesthetics and electroconvulsive therapies have been used with success, but evidence supporting the routine use is lacking.[231,232]

Status epilepticus is also associated with numerous systemic complications that can be related directly to the neurologic injury or associated with the treatments. Early management of acute hypoxic respiratory failure and associated acid-base imbalance can prevent secondary injury. Treatment of glucose abnormalities and early detection and treatment of infection can also prevent seizure recurrence. Myocardial depression from cardiotoxicity of seizure treatments may require additional cardiac monitoring and vasopressor support. Traumatic injury, rhabdomyolysis, and renal dysfunction should be monitored in patients with prolonged convulsions. Many of the antiepileptic medications can cause ileus, hypomotility, and potentially gut ischemia.[233]

Neuromuscular Disease

Neuromuscular diseases involving the muscle, nerve, and neuromuscular junction can pose unique challenges for the anesthesiologist in the ICU. We will review two common diseases that may require critical care management.

GUILLAIN-BARRÉ SYNDROME

Guillain-Barré syndrome (GBS) is a common cause of acute, severe neuropathy occurring at a rate of 1 to 2 cases per 100,000 persons per year worldwide. The incidence increases with age and is more prevalent in men. Because of the associated complications, including respiratory failure, GBS is one of the neurologic causes of admission to critical care units. Although GBS is associated with low overall mortality (6.9%), mortality increases with the need for mechanical ventilation (14.3%). These patients tend to have a higher incidence of cardiorespiratory arrest before ICU admission, prolonged ICU length of stay, and higher severity of illness scores.[234-236]

Several distinct clinical variants are associated with the syndrome, including acute inflammatory demyelinating polyneuropathy (AIDP), acute motor axonal neuropathy (AMAN), acute motor-sensory axonal neuropathy (AMSAN), and Miller-Fisher syndrome (MFS). The classic and most common variant of GBS is AIDP that typically manifests as a relatively symmetric, ascending muscle weakness that can progressively lead to severe flaccid paralysis and respiratory failure affecting 20% to 30% of cases. More than half the patients have a recent history of bacterial or viral infection. *Campylobacter jejuni* is the most frequently observed pathogen, along with cytomegalovirus, Epstein-Barr virus, and herpes simplex virus.[237] Regional variation has been associated with higher rates of infectious exposures, including recent association with the Zika and chikungunya viral epidemics.[238] GBS may also display sensory and autonomic features, depending on the subtype, and variation in speed of onset and offset. The AMAN variant is usually associated with *C. jejuni* infections, and the severe limb weakness is related to the autoimmune antibody response against GM1 and GD1a gangliosides. Similarly, with the MFS variant, anti-GQ1b antibodies can cause symptoms affecting the cranial nerves resulting in the clinical triad of ophthalmoplegia, ataxia, and areflexia.[235]

Commonly, the preceding infection or other immune response triggers an autoimmune reaction to peripheral nerves and spinal roots. Within 1 to 2 weeks after exposure, symptoms progress over several days to reach their peak at 2 to 4 weeks, with a plateau thereafter. In approximately 5% of patients, GBS progresses more rapidly, with maximal loss of function within 72 hours of symptom onset. At 4 weeks, most patients have progressed to the limit of their symptoms, and improvement is observed to start soon thereafter. However, recovery may be protracted for months to years depending on the extent of nerve injury.[239,240]

Investigations should include electrocardiography, CSF protein (for acellular protein elevation), electrophysiologic studies (axonal degeneration is associated with poorer recovery), and antibody status or screening for possible causative pathogens as well as prognosis. GM1 antibody is associated with worse recovery.[240]

Loss of ventilatory efficacy is often the main reason for admission to the ICU. A forced vital capacity of less than 20 mL/kg is a sensitive indicator of need for observation, and 15 mL/kg for probable intubation, along with maximal inspiratory pressure (MIP) less than -30 cm H_2O and clinical signs of fatigue and airway compromise. Hypercarbia is a relatively late sign, and the clinician should not rely on it. The Erasmus GBS Respiratory Insufficiency Score (EGRIS) is a validated tool to assist in prediction of which patients may benefit from early admission to the ICU based on severity of weakness, timing of symptoms, and bulbar symptoms.[241] Similarly, predicting successful weaning occurs in younger patients with milder symptoms and evidence of rapid improvement. Early tracheostomy in identifiably prolonged respiratory failure cases is appropriate.[242]

Dysautonomia is seen in up to 20% of patients and is a source of morbidity.[240] ICU level monitoring should also be considered for GBS patients with autonomic nervous system involvement that can cause cardiac arrhythmia, blood pressure lability, uncontrolled sweating, temperature dysregulation, ileus, and bladder dysfunction.

Supportive care in the ICU is important for patient outcomes, including DVT prophylaxis, early mobilization and rehabilitation, nutrition, and psychosocial support. Specific challenges to management are the problems of deafferentation pain and psychiatric depression. The pain can be severe, is truncal in distribution, and may respond to anticonvulsants more than opiates. It certainly contributes to the frequently observed depression. This pain is often magnified by immobility, boredom, and the limited ability of busy staff to engage actively with a cognitively intact patient.[240]

Both symptom limitation and recovery from GBS have been improved with the use of plasmapheresis or intravenous immune globulin (IVIG). No advantage is seen with one treatment approach over the other or in combination. However, many physicians try them sequentially in cases of treatment failure. In patients with acute respiratory failure, persistence of lack of foot flexion at the conclusion of immunotherapy is an indicator of prolonged mechanical ventilation.[243] Neither interferon nor corticosteroid use has been shown to improve outcome, either alone or in combination with immunotherapy, but newer immune modulation drugs are currently in clinical trials.[244]

MYASTHENIA GRAVIS

Several disorders affecting the neuromuscular junction, including toxins and immune-mediated and genetic syndromes, can cause skeletal muscle weakness. Myasthenia gravis (MG) is the most common of these disorders. Although the majority of patients with MG have autoantibodies against the muscle nicotinic acetylcholine receptor (AChR-Ab), some patients will have autoantibodies to muscle-specific tyrosine kinase (MuSK-Ab) or lipoprotein-related protein 4 (LRP4). Myasthenia itself has a strong association with various autoimmune conditions (e.g., thyroid disease, pernicious anemia, and rheumatoid arthritis), as well as being linked to women with certain human leukocyte antigen types.[245,246]

Although MG is a relatively rare disease (incidence of 4 to 12 per million person years and prevalence of 40 to 180 per million worldwide), it is relevant to neurocritical care in that patients can present acutely in myasthenic crisis with rapid deterioration of muscle function and ventilatory failure. Typical of autoimmune diseases, MG occurs in young adult women, with a mean age of 30. There is also a late onset presentation in men with mean age over 50 years. Modern management with immunosuppression and supportive treatment has led to improved prognosis with overall mortality rates of 2.2% to 4.5%, including recent lower ICU mortality rates of 5.3%.[247,248]

The myasthenic crisis can be precipitated by a progression in severity of the disease state or often by amplification by another factor. This factor can include infection, recent surgery, or interruption of immunosuppressants. Many drugs can exacerbate myasthenic crisis, including aminoglycosides, fluoroquinolones, anticonvulsants (including phenytoin), steroids, β-blockers, calcium channel antagonists, ketamine, lidocaine, neuromuscular blockers, and anticholinergic agents.[249]

The diagnosis should be suspected in patients with variable weakness, including respiratory, ocular, and bulbar muscles. Diagnostic workup is often to exclude GBS, brainstem stroke, organophosphate poisoning, and botulism. Tests should include electrophysiologic studies (helpful in seronegative cases), CSF protein, edrophonium response (less commonly used), and autoantibody testing to AChR and MUSK and LRP4. Subtyping by autoantibody type is increasingly important for diagnosis and management.[245]

The presentation is typically that of acutely worsening weakness of the respiratory or pharyngeal muscles. The patient should be observed closely for signs of impending respiratory failure. Forced vital capacity is useful, with 15 mL/kg being a useful trigger for intubation.[250]

Symptomatic treatment with acetylcholinesterase inhibitors is often diagnostic as well as therapeutic, balancing improvement in weakness with side effects from cholinergic stimulation. The other mainstay of therapy is immunomodulation. Typically, IVIG or plasmapheresis is started quickly to limit progression of severe generalized symptoms and avert frank crisis. Corticosteroids do have a role in establishing longer-term control of immunosuppression because IVIG and plasmapheresis have limited duration of efficacy. Corticosteroids alone are associated with a transient worsening of symptoms, before improvement, so they are best used concurrently with or immediately after plasmapheresis or IVIG. Chronic management typically involves tapering to low doses of prednisone with addition of a glucocorticoid-sparing immunomodulating agent (azathioprine, mycophenolate mofetil, cyclosporine, or tacrolimus) if necessary. Newer immunosuppression agents, including complement inhibition, are potentially new strategies.[251]

Central Nervous System Infection

Meningitis and encephalitis can be life threatening neurologic emergencies that require critical care management. Inflammation of the meninges and/or the brain can have multiple etiologies with CNS infections being the most common and having significant morbidity and mortality. Early recognition and treatment particularly of bacterial meningitis and herpes encephalitis can improve patient outcomes. The global burden of CNS infection disproportionately impacts lower-income countries. For bacterial meningitis, there are an estimated 3 million cases each year with the highest incidence of 85 cases per 100,000 persons in low income versus 6 cases per 100,000 persons in higher income countries.[252]

MENINGITIS

Meningitis is a serious condition producing inflammation of the leptomeninges covering the CNS. The causative pathogens differ among different patient populations. Community infections are frequently caused by *Streptococcus pneumoniae, Haemophilus influenzae, Listeria monocytogenes, Neisseria meningitidis,* and group B streptococci. *N. meningitidis* is particularly evident in teenagers. Since the advent of childhood vaccination programs, meningitis has become quite rare in high-income countries, with the highest incidence in children under the age of 1. In low-income countries, poverty and poor access to health care have led to persistently high rates of infection with regional differences in the pathogens reported. In the United States, *H. influenzae* affects mainly adults, but other organisms tend to affect all age groups. Worldwide, *S. pneumonia* and *N. meningitidis* are the most common pathogens in adults. Viral infections typically have a more subacute presentation. Fungal meningitis should be considered in immunocompromised patients. Nosocomial infection, in contrast, predominantly arises in the neurosurgical patient, especially with the use of ventricular devices, and the pathogens here comprise gram-negative rods and staphylococci.[253]

Initial assessment should include basic resuscitation, attention to airway management in patients with low GCS, and assessment of sepsis. Diagnostic features include fever, almost invariably with the classic nuchal rigidity and change in mental status; less often, photophobia, papilledema, and new-onset seizures may be seen. A rash is typical of meningococcal infection. Tests should include CSF cell count, protein, glucose, Gram stain, and culture, but any previous antibiotic dosing can diminish sensitivity, although polymerase chain reaction (PCR) testing using amplification may be able to identify small amounts of DNA in a sample. Viral PCR, immunoglobulin, fungal antigens, and cultures can also be considered. Opening pressure should always be recorded when possible. A CT scan should delay the lumbar puncture only when the patient's history suggests a previous mass lesion, stroke, or focal infection, recent seizures, or immunocompromised state.[254] Similarly, signs of papilledema, depressed level of consciousness, or focal deficit indicate a need for a CT examination to avoid herniation. Cerebral edema can develop in patients with meningitis and can lead to acute deterioration in mental status. ICP monitoring may be indicated.[255]

Treatment should be instituted quickly, delaying only to obtain emergency samples for Gram stain and culture. If no identification is possible on Gram stain, empiric antibiotic therapy should be delivered with third-generation cephalosporins (e.g., ceftriaxone or cefotaxime), along with vancomycin, until organism identification and sensitivities are obtained. This approach covers many of the community-acquired pathogens but should be tailored to individual patients and other potential pathogens. Nosocomial or trauma-associated infections may need broader spectrum antibiotic coverage. Steroids are useful adjuncts in bacterial meningitis and have been shown to reduce complications but not overall mortality.[256,257] The outcome of meningitis is a function of patient-related factors, the pathogenicity of the organism, and the time to effective treatment.

ENCEPHALITIS

Encephalitis manifests with fever, headache, and alteration of consciousness. Patients may also have delirium, focal deficit, and, commonly, seizures. Nuchal rigidity may be present in a mixed meningoencephalitis picture but should be absent in isolated encephalitis. Accompanying identifiers may be a vesicular rash associated with herpes zoster (although its absence does not remove zoster from the differential diagnosis), bilateral paralysis typical of West Nile disease, parotitis if mumps is suspected, and, of course, the hyperactivity, hydrophobia, and pharyngeal spasm of rabies.[253,258]

Many nonviral and noninfectious causes of encephalitis may confound the diagnosis. These include an expanding group of autoimmune encephalitis, vasculitis, systemic lupus erythematosus, stroke, rickettsial and parasitic infection, and drug-induced meningitis. Careful examination of clinical features, history, and laboratory data is necessary. CSF should be drawn for viral DNA PCR as well as the routine biochemistry, culture, and cell count. MRI with contrast is useful in identifying the demyelination and edema that can be difficult to see on CT. Serum serology is helpful for the diagnosis of Epstein-Barr virus, mumps, and West Nile disease as sources of encephalitis. Paired samples are recommended to allow later comparison if CSF PCR is unhelpful. Brain biopsy was considered the gold standard but is now a last option, after CSF PCR, culture, and serology have proven negative.[259]

Herpes simplex type 1 infection carries a very poor outlook if it is not treated expeditiously, and a course of empiric intravenous acyclovir is recommended until herpes infection has been excluded. Treatment for other viral etiologies is mainly supportive, including respiratory care and seizure management.[255] Other mosquito-borne viral infections such as West Nile and Zika have been increasing globally.

The pathogen mostly remains unidentified, and outcome usually then depends on classification of the clinical features, with intractable seizure and cerebral edema carrying a poor prognosis. Self-limiting seizure usually indicates a swift recovery. The advent of high-throughput DNA sequencing has advanced the ability to detect viral pathogens and potentially virus discovery in cases of unexplained meningitis and encephalitis.[260]

Postoperative Neurosurgical Care

Many neurosurgical procedures are lengthy and involve significant insult to the brain. Thus, postoperative ICU admission is necessary to avoid secondary insult and monitor postoperative complications like intracranial rebleeding, cerebral edema, or seizures. The incidence of post-craniotomy bleeding of 0.5% is associated with increased blood pressure during and after surgery (SBP >160 mm Hg; MAP >110 mm Hg) and mainly occurs during the first 24 hours.[261]

The patient should be extubated immediately after surgery if possible because a full clinical and neurologic evaluation of the awake patient is the best way to detect post-craniotomy complications. Exceptions are possibly extremely long operations, low preoperative GCS, major surgery in the posterior cranial fossa or close to the brain stem, or a high risk for the development of cerebral edema. The incidence for postoperative complications is higher in patients with intraventricular tumors.[262] Early extubation in combination with close neurologic monitoring is safe and omits the need for routine postoperative CT.[263] In patients where a planned extubation cannot be performed within 1 hour after surgery, an immediate CT should be performed, as these patients have a high risk for postoperative complications and may need emergency neurosurgical interventions.[263]

Pain is often underestimated after craniotomy and narcotics are avoided due to the fear of hypoventilation, which might increase ICP.[264] Therefore, a careful evaluation of pain using the visual analog scale and adequate therapy with nonsteroidal antiinflammatory drugs and opioids must be initiated. A scalp block with local anesthetics also reduces postoperative pain.

Patients after craniotomy have a high risk for postoperative nausea and vomiting. As retching and vomiting are extremely unpleasant for the patient and additionally increase the risk of rebleeding, pharmacologic prevention with selective serotonin antagonists (e.g., ondansetron and granisetron) in combination with low-dose corticosteroids should be used.[265]

DVT and pulmonary embolism occur in 3% of the patients up to 30 days after craniotomy with a peak at the third postoperative day. Prophylaxis with heparin can be initiated in most cases 1 day after surgery.[266,267]

BRAIN DEATH

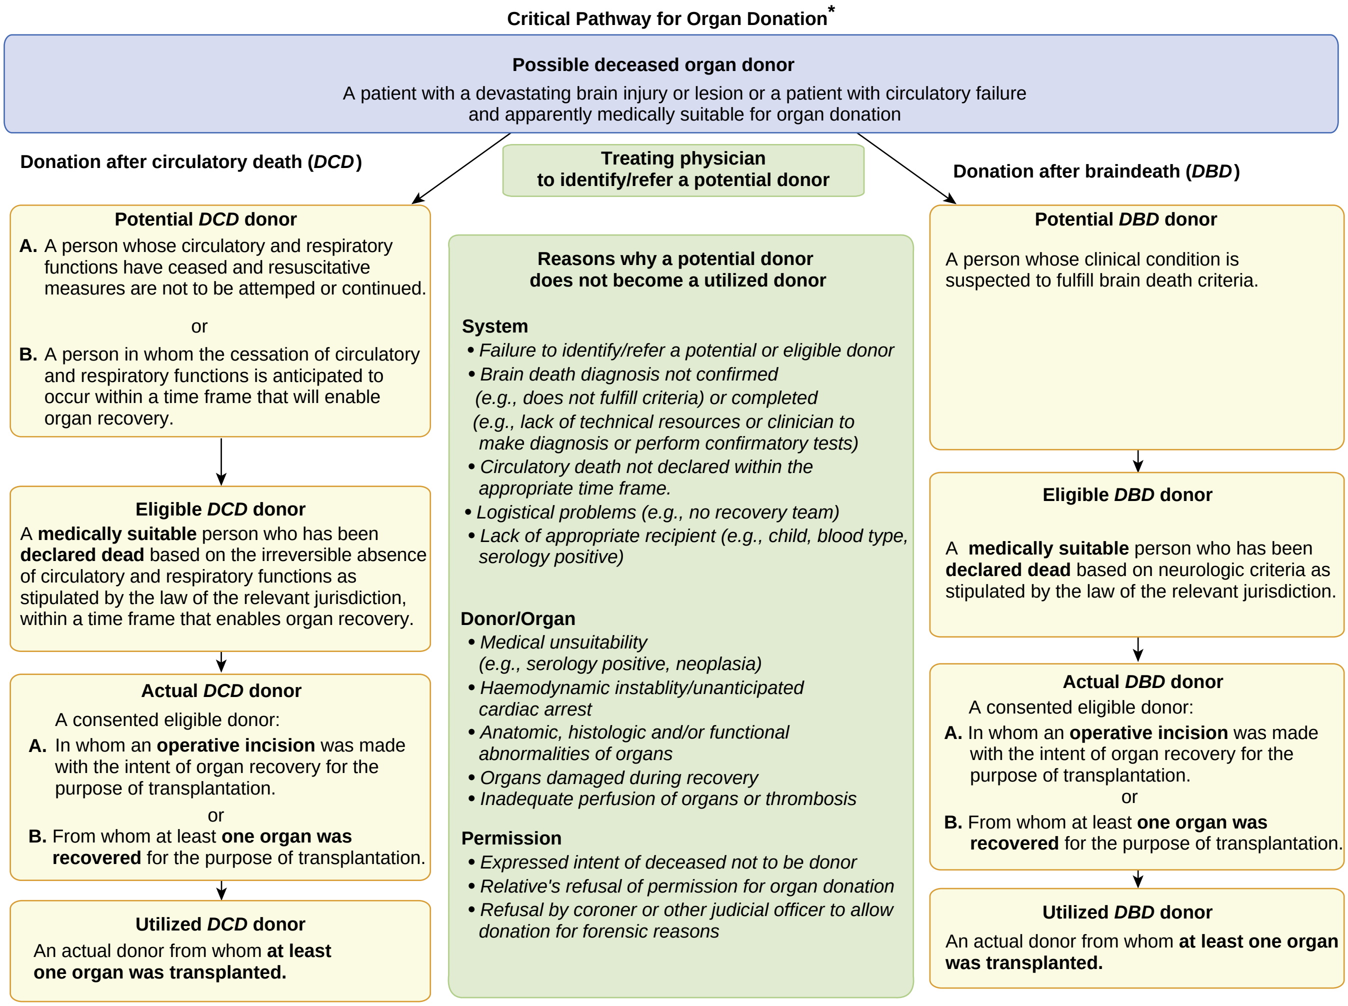
The diagnosis of brain death remains one of the most challenging and controversial areas of neurocritical care. Physicians must have adequate training and understanding of the principles of brain death declaration and be able to apply them assiduously and without compromise (see Chapter 83).

Declaration of brain death was originally codified by the Harvard criteria in 1968, with subsequent modification to allow separation of cerebral death from death of the entire nervous system, including the spinal cord.[268,269] The diagnosis is built on a thorough clinical examination of nervous system function, involving evaluation of the reflex response of the brain and cranial nerves to hypercarbia, pain, light, temperature change, attitudinal change of the middle ear, and detection of the blink, cough, and gag reflexes. The mechanisms for the irreversible cause of neurologic dysfunction should be clear. The examination must be done in circumstances of adequate systemic oxygenation and perfusion. Confounders, such as hypothermia, metabolic or endocrine compromise, and persistent sedative or neuromuscular drugs, must be corrected. One of the tests should include an appropriately conducted apnea trial in the presence of the responsible physician, with confirmation of adequate changes in $PaCO_2$. If for any reason any test cannot be completed in a safe manner or to the satisfaction of the responsible physician(s), then an ancillary test should be performed based on standard policies. The hospital should have an institutionally approved protocol for brain death declaration and the conduct of any ancillary tests. In addition, mechanisms for regular review and quality improvement are essential.

Proper training and knowledge of administrative and legal policies are essential, as there may be differences across hospitals, regions, and countries. Guidelines on the examination and examiner may be different in adult versus pediatric cases).[270,271] In addition, physician qualifications may vary by training in neurology, neurosurgery, or neurocritical care. Perhaps more important than the diagnosis of brain death is communicating with the care team and the family.

Ethical Considerations

Ethical issues are frequently encountered in a neurocritical care unit (see Chapter 8). Unfortunately, significant life-altering morbidity can occur, to the extent that many patients and families would not prefer aggressive therapy.[272] This can be a difficult concept to accept for the physician, whose aim is to heal and preserve life. However, the ethical imperative in Western culture is to preserve the autonomy of the individual (along with the principles of nonmaleficence, beneficence, and justice), and this has been extended to health care decision making. This situation may lead to uncomfortable choices and communication within the health care team, whose members may



Critical Pathway for Organ Donation*
Possible deceased organ donor
A patient with a devastating brain injury or lesion or a patient with circulatory failure and apparently medically suitable for organ donation
Donation after circulatory death (DCD)
Treating physician to identify/refer a potential donor
Donation after braindeath (DBD)
Potential DCD donor
A. A person whose circulatory and respiratory functions have ceased and resuscitative measures are not to be attemped or continued.
or
B. A person in whom the cessation of circulatory and respiratory functions is anticipated to occur within a time frame that will enable organ recovery.
Eligible DCD donor
A medically suitable person who has been declared dead based on the irreversible absence of circulatory and respiratory functions as stipulated by the law of the relevant jurisdiction, within a time frame that enables organ recovery.
Actual DCD donor
A consented eligible donor:
A. In whom an operative incision was made with the intent of organ recovery for the purpose of transplantation.
or
B. From whom at least one organ was recovered for the purpose of transplantation.
Utilized DCD donor
An actual donor from whom at least one organ was transplanted.
Reasons why a potential donor does not become a utilized donor
System
• Failure to identify/refer a potential or eligible donor
• Brain death diagnosis not confirmed (e.g., does not fulfill criteria) or completed (e.g., lack of technical resources or clinician to make diagnosis or perform confirmatory tests)
• Circulatory death not declared within the appropriate time frame.
• Logistical problems (e.g., no recovery team)
• Lack of appropriate recipient (e.g., child, blood type, serology positive)
Donor/Organ
• Medical unsuitability (e.g., serology positive, neoplasia)
• Haemodynamic instablity/unanticipated cardiac arrest
• Anatomic, histologic and/or functional abnormalities of organs
• Organs damaged during recovery
• Inadequate perfusion of organs or thrombosis
Permission
• Expressed intent of deceased not to be donor
• Relative's refusal of permission for organ donation
• Refusal by coroner or other judicial officer to allow donation for forensic reasons
Potential DBD donor
A person whose clinical condition is suspected to fulfill brain death criteria.
Eligible DBD donor
A medically suitable person who has been declared dead based on neurologic criteria as stipulated by the law of the relevant jurisdiction.
Actual DBD donor
A consented eligible donor:
A. In whom an operative incision was made with the intent of organ recovery for the purpose of transplantation.
or
B. From whom at least one organ was recovered for the purpose of transplantation.
Utilized DBD donor
An actual donor from whom at least one organ was transplanted.

**The "dead donor rule" must be respected. That is, patients may become donors only after death, and the recovery of organs must not cause a donor's death.*

Fig. 84.8 The critical pathways for organ donation after brain death and donation after circulatory death, as published by the World Health Organization. (From Dominguez-Gil B, Delmonico FL, Shaheen FAM, et al. The critical pathway for deceased donation: reportable uniformity in the approach to deceased donation. *Transplant Int.* 2011;24:373.)

have differing opinions on goals as well as the patient and relatives, who, again, may think very differently.

Certain strategies can avoid or minimize these difficulties:

- Prognosis should be made based on the best available evidence. This may involve planning and discussion among the team members in advance of family meetings. Personal anecdotes should be avoided, even if solicited.
- The relationship within the team should be open and collegial, with mutual respect given to the principle of open discussion. This approach avoids misperception of goals and attitudes and enables more consistent communication with families, who often find dissonance among members of the ICU team disturbing.
- The presence of an advance directive offers major benefits, and the neurocritical care unit should have an admissions protocol that includes asking all competent, conscious patients to consider making their attitudes or wishes known.
- Regular family and patient conferences allow communication of prognosis and offer the opportunity for correction of any misconceptions, as well as progressive education of the family members to anticipated problems.
- Internal institutional mechanisms for raising concerns and conducting reviews should be in place. This is often facilitated by the presence of an institutional ethics committee, whose members can examine the issues, promote educational discussion, and help achieve consensus.
- All decision making should be documented carefully and completely.
- Orders for limitation or withdrawal of therapy should be written explicitly, and institutional protocols should be used wherever possible.

Other important areas of possible conflict exist that are not possible to address within the confines of this text, but readers are advised to educate themselves on these and include the following:

- The issues surrounding organ donation from the brain dead and the non-heart-beating donor (Fig. 84.8)
- Withdrawal of care for the incompetent patient without family
- Hospital bylaws and state legislation on the certification of death, whether that be by neurologic or cardiovascular criteria

Conclusion

Neurocritical care demands a thorough comprehension of the physiology, pharmacology, and pathology of the nervous system as well as for the organ systems supporting it. The best care is provided in circumstances that allow multidisciplinary collaboration and appropriate attention to detail of often complex and demanding pathologic processes but integrating them optimally under the direction of the critical care physician.

Extracorporeal Membrane Oxygenation and Cardiac Devices

JAMES G. RAMSAY, KENNETH SHELTON, and GASTON CUDEMUS

KEY POINTS

- Extracorporeal membrane oxygenation (ECMO) consists of a specific heart-lung machine that provides circulatory support and/or gas exchange for patients with severe but potentially reversible respiratory or cardiac failure or both. Although the term *extracorporeal life support* (ECLS) might describe the system more accurately, ECMO is actually most often used and universally accepted for describing all its applications.
- Different configurations of ECMO (e.g., venovenous [VV], venoarterial [VA], venous to pulmonary artery [V-PA]) can be utilized depending on specific organ failure and severity (e.g., respiratory failure, cardiogenic shock, cardiogenic shock associated with respiratory failure, respiratory failure in association with right ventricular failure). The most rapid way to initiate ECMO urgently (excluding patients undergoing cardiac surgery) is peripheral VA cannulation.
- ECMO must be viewed as a "bridging" therapy where the anticipated outcome is either recovery or replacement of the failing heart, lung, or both. Assessment of the likelihood of survival using recently published scoring systems, and of the patient's potential candidacy for transplant or device (cardiac) should be made prior to initiation. Ideally the decision to proceed with ECMO should be made by a team rather than an individual.
- Overall survival of VV ECMO to recovery is now approximately 60% in adults with acute respiratory distress syndrome (ARDS), usually due to viral or bacterial infection, whereas survival of VA ECMO in adults with severe cardiac failure is approximately 40%. Where ECMO is urgently initiated in the setting of *extracorporeal* cardiopulmonary resuscitation (ECPR) survival in adults is 29%.
- Vascular access is a critical aspect of ECMO as different sites are associated with different characteristics of flow and gas exchange in combination with the patient's native heart and lung functions. Vascular complications are common, with arterial complications more frequent and severe than venous complications.
- Anticoagulation management is institution specific, varying by the nature of the circuit (how much of the ECMO circuit is heparin bonded), flow (greater anticoagulation needed for lower flows), and which coagulation tests are readily available. Bleeding and clotting complications are common.
- The cardiac anesthesiologist plays an important role in the cannulation and decannulation of patients, managing sedation and cardiac support medications for urgent bedside procedures, anesthesia for operative procedures, and in providing echocardiographic assessment of cannula placement and cardiac function. The anesthesiologist-intensivist is an integral part of the management team in the intensive care unit (ICU), providing a continuum of care through ECMO management and potential transition to advanced therapies both in the ICU and the operating room.

Introduction

Extracorporeal membrane oxygenation or ECMO refers to a number of configurations of extracorporeal circulatory and/or respiratory support. As the technology evolved, other acronyms such as MCS (mechanical circulatory support) and ECLS (extracorporeal life support) have been used, but in North America ECMO continues to be the most commonly used term to describe a circuit, pump, and oxygenator that can perform the work of the heart and lungs by adding oxygen and removing carbon dioxide from circulating blood for prolonged intervals. Venovenous (VV) ECMO withdraws venous blood and returns oxygenated blood to the right side of the heart supporting only respiration; venoarterial (VA) ECMO withdraws venous blood and returns oxygenated blood to the arterial system, thereby supporting both respiration and circulation. Another configuration is venous-pulmonary artery (VPA) ECMO used to support the right heart and the lungs when there is right heart failure and respiratory failure but the left heart is not supported.

An ECMO circuit comprises cannulae inserted into large vessels to remove and return the blood from the patient,

tubing to connect to a nonpulsatile centrifugal pump that generates blood flow, and an oxygenator, where an oxygen-air mixture flows through the blood, referred to as the "sweep." This is a closed system without a reservoir, with some or all of the circuit components surface bonded with heparin, and is designed for extended use, such as days or weeks. This is in contrast to the extracorporeal circuit used for cardiopulmonary bypass (CPB) in the operating room that uses larger-diameter and longer tubing (larger "prime" volume), and is an open system with a reservoir designed to receive input not only from the venous cannula but also from the operative field. Such CPB circuits may or may not be heparin bonded, and are intended for surgical use of short duration (e.g., hours). There is some evidence in the lung transplant literature that use of ECMO during the surgical procedure may be associated with a smaller systemic inflammatory response than the use of the traditional CPB.[1]

Pumpless extracorporeal lung assist (pECLA), or the Novalung, uses the patient's arterial pressure rather than a pump to drive blood through an extracorporeal oxygenator. It therefore supports only respiration. This device requires less anticoagulation than traditional ECMO but due to lower flows and the membrane area also has a more limited capacity especially for oxygenation.[2] It has been used to support patients with pulmonary hypertension awaiting lung transplantation, implanted in a pulmonary artery to left atrium configuration.[3] It is available in North America but is less widely used than ECMO and will not be discussed further.

History of Extracorporeal Cardiorespiratory Support

The history of ECMO is inextricably bound to the development of CPB for cardiac surgery. The first successful use of CPB in a human was by Gibbon in 1953, to repair an atrial septal defect in an 18-year-old patient.[4] The following year, Warden and colleagues reported cardiac surgery using extracorporeal circulation,[5] after which there was an ever increasing number of reports from many centers. Among the major limitations in these early reports was the use of "bubble" oxygenators where oxygen is bubbled through a reservoir of blood to achieve gas exchange. These oxygenators are associated with trauma to formed elements of the blood and coagulopathy with prolonged use.[6] The development of oxygenators with membranes separating flow of the respiratory gases from the blood reduced these effects, making the oxygenators suitable for longer-term use. Membrane oxygenators have replaced bubble oxygenators in cardiac surgery and their development led to the first successful reports of prolonged support outside of the operating room, in 1972 by Hill and associates[7] in a 24-year-old trauma patient, and by Bartlett after neonatal cardiac surgery.[8] In 1985 Bartlett and associates reported the successful use of ECMO for neonatal respiratory failure in 11 patients.[9] In the following two decades a number of additional trials showed the benefit of ECMO in neonatal respiratory failure, the most definitive of which was published in 1996 by the UK Collaborative ECMO Trial Group in 185 infants.[10] In the same year Green and colleagues[11] published a trial demonstrating similar benefit in older pediatric patients with respiratory failure. Note the majority of use in the first decades was for respiratory failure, using VV ECMO. During this period the Extracorporeal Life Support Organization or ELSO was founded, first at the University of Michigan in 1989, then a European ELSO group formed in 1991. This organization has played a key role in documenting worldwide ECMO use, and pioneering education, research, and development in all types of ECMO support in all populations. Fig. 85.1 and Table 85.1 illustrate the increase in use of ECMO and the survival data since 1990 (www.ELSO.org).

TABLE 85.1 International Registry of ECMO; Survival from ECMO and from Hospitalization, by Age Category (Neonatal, Pediatric, or Adult) and Indication (Pulmonary, Cardiac, or "ECPR" [ECMO for Cardiopulmonary Resuscitation])

	OVERALL OUTCOMES		
	Total Runs	**Survived ECLS**	**Survived to DC or Transfer**
Neonatal			
Pulmonary	30,934	25,990 (84%)	22,662 (73%)
Cardiac	7,794	5,063 (64%)	3,281 (42%)
ECPR	1,718	1,140 (66%)	708 (41%)
Pediatric			
Pulmonary	8,820	5,953 (67%)	5,131 (58%)
Cardiac	10,462	7,177 (68%)	5,447 (52%)

BOX 85.1 **Indications for VV ECMO**

- Severe ARDS
  - Murray score of 2.5[19]
  - Berlin definition[20]
- Respiratory failure associated with:
  - Refractory hypoxemia despite maximum less invasive therapies
    - e.g., FiO_2 >90%, PEEP >15 cm H_2O, prone ventilation
    - Refractory hypercarbia (e.g., $PaCO_2 > 80$) with acidosis
    - Injurious ventilating pressures (e.g., plateau pressures >30 mm Hg) with lung-protective tidal volumes
- Common clinical conditions
  - Severe pneumonia (viral or bacterial)
  - Aspiration pneumonitis
  - ARDS from any cause
  - Pulmonary contusion
  - Status asthmaticus
  - Severe air leak syndrome
  - Inhalation injury
  - Airway obstruction (e.g., mediastinal mass)
  - Pre and post lung transplant

ECMO for Respiratory Failure (VV ECMO)

In contrast to the ECMO experience in neonatal and pediatric respiratory failure as previously described, demonstration of benefit in adults took much longer, delayed in part due to the publication of a trial in 1979 by Zapol and associates[12] in 90 adult patients with respiratory failure. This trial had many limitations, including the use of VA rather than VV ECMO, patient selection, anticoagulation technique and bleeding complications, and the use of standard ventilation at the time—relatively high-tidal volume and low positive end-expiratory pressure (PEEP). Poor outcomes deterred adult use of ECMO for more than 20 years. From 2001 to 2006 a large, ambitious British trial, the CESAR trial, was performed to evaluate VV ECMO for respiratory failure in adults.[13] This study was performed during the H1N1 influenza pandemic, and involved transferring patients with severe respiratory failure to a central expert ECMO center, where they were randomly assigned to ECMO or standard therapy. Despite some methodological and statistical limitations, the results supported the use of ECMO performed in a specialized center to improve survival: 63% versus 43% survival with ECMO versus standard treatment. At the same time, another report (case series) of VV ECMO in adults with severe acute respiratory distress syndrome (ARDS) due to H1N1 was reported from Australia and New Zealand (ANZ ECMO).[14] This study found a 79% survival at 30 days in patients who received ECMO. Recently a large multicenter trial of VV ECMO in adults with severe ARDS, the EOLIA trial, was published in 2018,[15] with the authors concluding no difference in mortality between ECMO and conventional therapy at 60 days: 35% versus 46% ($P = .09$), with 28% of the control group crossing over to ECMO after randomization and a 57% mortality in this crossover group. Editorial comments on this study have challenged this conclusion, maintaining that it supports the use of early ECMO in adults with severe ARDS.[16,17] The ELSO database reports survival to discharge with ECMO for adult respiratory failure as 60% with this percentage being relatively stable over 15 years.[18]

INDICATIONS FOR VV ECMO IN RESPIRATORY FAILURE

Box 85.1 lists common indications for VV ECMO in respiratory failure. As VV ECMO supports only respiratory function, if the patient has right- or left-sided cardiac failure then another configuration of support must be used. The most common indication is ARDS, most commonly due to viral or bacterial infection. As indicated previously, the most studied population is patients with H1N1 viral pneumonia. A commonly used assessment for the severity of ARDS is the Murray score, which is based on four standard criteria: PaO_2/FiO_2 gradient for oxygen, degree of PEEP, number of quadrants affected as shown on the chest radiograph, and lung compliance.[19] In 2012, the Berlin criteria were published, where the severity of ARDS is rated as mild, moderate, or severe based on the PaO_2/FiO_2 gradient for oxygen if other criteria are present.[20] In general, patients with severe ARDS (PaO_2/FiO_2 gradient of < 100 mm Hg with PEEP > 5) are potential candidates for ECMO as the mortality without ECMO is approximately 40%.[20] As described later in the section on the ethics of ECMO, there are studies that evaluate the likelihood of survival at the time ECMO is being considered; this can help guide decision making. It should also be mentioned that from the CESAR trial described earlier,[13] if a patient being considered for VV ECMO is not at an ECMO center or one with expertise in management of ARDS, transfer to such a facility is likely to provide a better outcome even in the absence of ECMO. While not formally studied, many reports indicate that outcomes are better with earlier institution of ECMO, probably at least in part because this permits the use of lung protective ventilation when respiration is supported by ECMO.[21]

ECMO for lung transplantation is discussed in the next section.

BOX 85.2 **Indications for VA ECMO**

- Cardiogenic shock
  - Hypotension/poor tissue perfusion despite maximum medical therapy +/– balloon pump
- Combined cardiorespiratory failure
  - Cardiogenic shock with pulmonary edema and hypoxemia
- Urgent ECMO for respiratory failure
  - As temporizing measure before institution of VV ECMO
- Common clinical conditions
  - Refractory cardiogenic shock (any cause)
  - Failure to separate from cardiopulmonary bypass
  - Bridge to durable ventricular assist device or transplant
  - Intraoperative lung transplant
  - Unstable arrhythmias
  - Anaphylaxis
  - Massive pulmonary embolus
  - Cardiac arrest without return of spontaneous circulation

VA ECMO, venoarterial extracorporeal membrane oxygenation; VV ECMO, venovenous extracorporeal membrane oxygenation.

CONTRAINDICATIONS TO VV ECMO

In keeping with ELSO guidelines[18] there are no absolute contraindications for VV ECMO in adults Box 85.2. There are, however, conditions known to be associated with a poor outcome, despite ECMO; these should always be considered before initiating ECMO assistance. These conditions include: injurious mechanical ventilation for 7 days or longer, major pharmacologic immunosuppression, and intracranial hemorrhage that is recent or expanding. Specific patient conditions should also be considered. Although no specific age is a contraindication, increased age is considered to increase the risk.[18] A body mass index (BMI) of more than 40 to 45 may be associated with technical difficulties and the risk of not being able to achieve an adequate blood flow. VV ECMO is a bridge to either recovery or lung transplant; if neither of these outcomes appears at all likely then its initiation is not advisable.

Extracorporeal Membrane Oxygenation for Patients Awaiting and Undergoing Lung Transplantation

The history of ECMO for severe respiratory failure as described previously refers mostly to patients with acute or acute on chronic disease where recovery could be anticipated. Another population is patients with end-stage chronic lung disease awaiting lung transplantation. These patients often have a slow (in years) deterioration in function and an increased need for oxygen support, with the final stage being an acute deterioration where standard therapy with mechanical ventilation ultimately fails. Institution of ECMO to prolong survival until transplant, use of ECMO during transplant surgery, and extension or initiation of ECMO postoperatively for primary graft dysfunction (PGD) or other indications have all become common applications for this advanced therapy. As recently as 2010 there was concern that the use of ECMO resulted in a reduced long-term survival from lung transplantation,[22] but this is no longer the case in 2018. Case reports, single center reports, and surveys have documented that the use of pretransplant ECMO, sometimes for months, was followed by successful transplant and good long-term outcomes.[23,24] Raleigh and associates compared 10 studies on the use of preoperative ECMO for lung transplant patients and found similar outcomes to the patients who did not need ECMO[25] and Loor and associates described factors that contributed to posttransplant survival in this population.[26] Intraoperative use of ECMO during the procedure has also been shown to reduce the inflammatory response and leads to less PGD when compared to CPB and leads to improved short-term and longer-term outcomes[1,26,27] even when compared to no use of either CPB or ECMO intraoperatively.[28] While preoperative ECMO may be VV, VA, or VPA, intraoperatively VA ECMO is usually used due to surgical manipulation of the heart with its attendant hemodynamic compromise as well as the need for one-lung ventilation in patients with end-stage pulmonary disease and elevated pulmonary vascular pressures. Postoperatively, ECMO support may be needed to support the new lungs in the face of PGD, the right heart, the left heart, or any combination of these. Postoperative ECMO support is also associated with excellent outcomes.[28]

ECMO for Circulatory Failure (VA ECMO)

VA ECMO can be used to support the heart and lungs temporarily in a patient with poor cardiac function who undergoes an invasive cardiology procedure, to continue postoperative cardiopulmonary support in a cardiac surgery patient who fails to separate from CPB, and in a patient with refractory cardiac failure with or without associated respiratory failure. These conditions may occur due to an acute recoverable illness (e.g., myocarditis) or may be in the setting of acute on chronic heart failure in patients being evaluated for long-term advanced therapies such as a durable ventricular assist device or cardiac transplant. Urgent use of ECMO in the acute setting of in-hospital cardiac arrest (ECPR) is also practiced in some centers. Finally, as VA ECMO can be instituted at the bedside without imaging, it may be the preferred technique for emergent cannulation in any form of respiratory or cardiac failure, with elective conversion to another form (e.g., VV ECMO) once the patient has stabilized.

The historical perspective for use of VA ECMO for cardiac or combined cardiorespiratory support in adults is illustrated in the 2016 report from the ELSO registry.[29] Adult cardiac ECMO was in its infancy in 1990 with little increase in use until 2006 when its use began to increase exponentially; there were more than 2000 adult cardiac ECMO runs reported to ELSO in 2015, comprising an ever-increasing proportion of all ECMO runs (Fig. 85.2). This exponential increase was likely fueled by consistent success in the neonatal and pediatric populations; improvements in the ECMO circuits, pumps, and oxygenators; and the success and experience with VV ECMO for adult respiratory failure. Overall survival in adults who receive ECMO for cardiac indications is approximately 40% with a slight increasing trend over the last 10 years.[29]

INDICATIONS FOR VA ECMO

For periprocedural support of the heart only, short-term devices such as a percutaneous left ventricular assist device

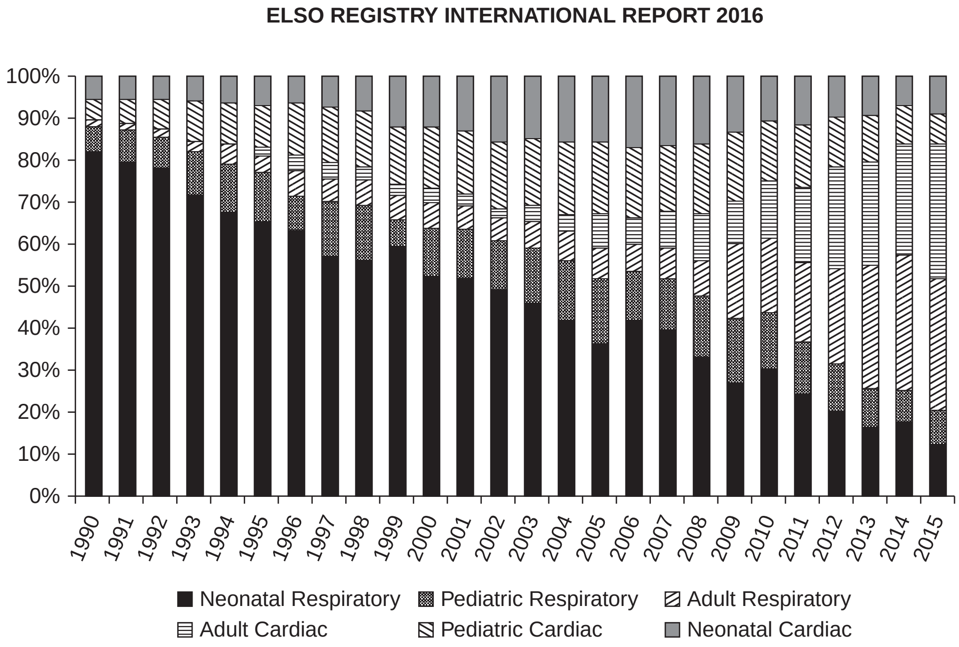

Fig. 85.2 Distribution of trends in extracorporeal membrane oxygenation (ECMO) utilization (data from the ELSO registry) by patient age and indication (pulmonary or cardiac) between 1990 and 2016. In the early years the majority of ECMO was neonatal respiratory, whereas in recent years it is more adult respiratory and cardiac. (From Thiagarajan RR, Barbaro RP, Rycus PT, et al. Extracorporeal Life Support Organization Registry International Report 2016. *ASAIO J*. 2017;63(1):60–67.)

(LVAD, e.g., Impella or TandemHeart) are one type of support; the other is short-term ECMO, usually peripheral (femoral) VA ECMO. Recent reviews of temporary circulatory support devices in cardiology compare and summarize risks, benefits, and outcomes with the different approaches in different settings.[30,31] Use of VA ECMO provides support for both the right and left heart, whereas short-term LVADs support only one ventricle. Surgeons are much more likely to use VA ECMO in the setting of postcardiotomy failure, partly due to familiarity with surgical cannulation (or the presence of central cannulae), but also due to the support this provides for both ventricles and the lungs. Reviews of postcardiotomy ECMO suggest approximately 30% survival to hospital discharge.[32,33]

For support of the patient with refractory end-stage cardiac failure who may be a potential candidate for durable LVAD or transplant, or who has already been evaluated for such advanced therapy, there are advantages and disadvantages to both the short-term LVAD (Impella or TandemHeart) and ECMO. Such patients always need left ventricular support but if right heart function and pulmonary function are adequate a short-term percutaneous LVAD might be appropriate. As discussed later, a significant advantage of these devices over VA ECMO is decompression of the left ventricle, which is not a feature of VA ECMO. If placed via the axillary/subclavian artery, the patient can be at least somewhat mobile with such a device. If, however the right heart, or lungs, or both, needs support, then VA ECMO is most appropriate. Another issue is urgency or acuity: peripheral VA ECMO can be initiated at the bedside without imaging more rapidly than a temporary assist device. The main problem if this support is needed for days or weeks is the femoral cannulae prevent mobilization. A recent systematic review (publications between 2006 and 2016) of short-term mechanical circulatory support as a bridge to durable LVAD or transplant (or recovery) documented a wide range in the number of days of support (individual study means of up to 47 days) and an overall 45% to 66% of patients surviving to discharge.[34] In this report where the support was via central ECMO (see later), a higher proportion of patients went on to receive durable LVAD or transplant and survived to discharge than those who received peripheral ECMO.

For acute recoverable myocardial illness such as myocarditis, survival is approximately 67% with VA ECMO.[35] This is a better outcome than for other cardiac indications, likely reflective of the younger age of such patients and possibly because in this setting ECMO is usually instituted before cardiogenic shock or arrest.

In the 2016 ELSO report, use of ECMO in the setting of cardiopulmonary resuscitation (CPR) or extracorporeal cardiopulmonary resuscitation (ECPR) in adults comprises approximately 15% of all adult ECMO.[29] Sixty-six percent of all centers reporting to the registry indicate some use in this setting. While referrals for ECMO for respiratory and cardiac failure are often relatively acute and urgent, in the setting of bedside CPR, ECMO needs to be instituted very rapidly; time from starting CPR to ECMO initiation is an important determinant of good outcome.[36,37] This limits its use to institutions able to support a team that is ready for such rapid activation. Survival to discharge is, not surprisingly, the lowest of all ECMO applications in both adults (29%) and pediatrics (41%).[29] The quality of evidence in published studies comparing ECLS to standard CPR is low, with a great deal of heterogeneity.[37]

Indications for VA ECMO are summarized in Box 85.2. According to the 2013 ELSO guidelines[18] the most common indication for VA ECMO in adult cardiac failure is the presence of cardiogenic shock with end organ hypoperfusion despite the use of dual inotropes and significant vasopressor requirement. This includes cardiogenic shock with or without myocardial infarction, fulminant myocarditis, peripartum cardiomyopathy, decompensated chronic heart failure, right heart failure, medication or toxic drug overdose, and postcardiotomy shock.

CONTRAINDICATIONS TO VA ECMO

Absolute contraindications to VA ECMO include acute intracranial hemorrhage or massive stroke, active bleeding, and severe aortic insufficiency. Relative contraindications (variable by center) may include contraindication for anticoagulation, advanced age, obesity, active cancer, suicide attempt, chronic hemodialysis, end-stage liver disease, aortic dissection, and lack of social support. As is the case for VV ECMO, if neither recovery nor candidacy for durable therapy (LVAD or transplant) are likely, VA ECMO should not be initiated.

The Ethics of Extracorporeal Membrane Oxygenation

The initiation of any form of ECMO is lifesaving when the heart, or lungs, or both are failing despite maximum medical therapies. It is a very invasive and labor-intensive therapy, with associated severe complications, and may confine a patient to an ICU for days, weeks, or even months. As the practice has evolved over time, many groups have tried to address issues of patient appropriateness, possible exclusion criteria, and prognosis before initiating the therapy. An essential consideration is that ECMO is a "bridge" to something else and cannot be viewed as a long-term solution; Box 85.3 lists the uses of ECMO as a "bridging" therapy to a variety of possible scenarios. The following discussion addresses only the individual patient ethical dilemmas, and not the overriding issue of the use of a limited availability, expensive, and labor-intensive therapy with its cost:benefit implications, and overall implications for health care systems.

BOX 85.3 Extracorporeal Membrane Oxygenation as "Bridge" Therapy

Bridge to Decision	Urgent initiation before the ability to assess likelihood of recovery or candidacy for advanced therapy
Bridge to Recovery	Initiation for organ failure that is believed to be potentially recoverable
Bridge to Advanced Durable Therapy	Initiation after acceptance for eligibility for device (e.g., VAD) or transplant
"Bridge to Nowhere"	Bridge to decision which is likely to be non-recovery and non-eligibility for advanced therapy

VAD, Ventricular assist device.

When an otherwise relatively young and healthy patient develops an acute severe illness resulting in acute cardiac failure and shock (e.g., viral cardiomyopathy) or acute refractory lung failure (e.g., viral pneumonia), the decision to initiate lifesaving extracorporeal support as a "bridge to recovery" seems relatively straightforward. Similarly, a patient with end-stage disease of any kind who already has a "do not resuscitate" status would likely not be a candidate for ECMO if the heart suddenly failed. Unfortunately, the clinical spectrum of potential candidates runs as a continuum between these two examples. From the patient and family, through all levels of caregivers and decision makers, tools to help assess the likelihood of successful outcome with this advanced therapy are needed.

The ELSO registry database has been used to study the likelihood of survival *prior to* ECMO initiation, both in respiratory failure (Table 85.2)[38] and cardiac failure (Table 85.3).[39] There are many common elements in these publications, including the duration and degree of respiratory support, age, other organ function, and acidosis. While these publications can be used as a general guide and can be quoted to referring physicians and families, they have to be placed in clinical context; decision making for life-sustaining treatment must be patient-specific. Courtwright and associates[40] make a point of the need to emphasize to the patient's family the "bridging" nature of ECMO therapy, and that a destination must be formulated at the outset or early on. Because of the need for anticoagulation and the risk for bleeding or thrombosis, patients who are not candidates for anticoagulation (e.g., intracranial hemorrhage) are generally not candidates for ECMO, even though more experience is accumulating with reduced or even no anticoagulation with the use of anticoagulant bonded cannulae, tubing, pump heads, and oxygenators. Patients with underlying severe disease who are not expected to survive more than some predetermined period (i.e., 6 months or a year) independent of the need for ECMO are unlikely to be considered as candidates. Rather than have a single physician or surgeon determine whether ECMO should be initiated in a given patient, especially when a request comes from an outside hospital, many institutions make this a shared decision by a small committee (i.e., 3 individuals) who are all familiar with and participate in ECMO management.[41]

Overall survival for adult respiratory and cardiac ECMO is approximately 60% and 40%, respectively. Although this is certainly a major advance for diseases that were previously not survivable, the other side of this coin is that mortality remains at 40% and 60%. It makes good sense to engage palliative care and/or an ethics committee and other counselling services, where available and appropriate, at the outset for this therapy.[40,41] When ECMO is being considered but there is uncertainty about the likelihood of recovery or candidacy for advanced durable therapy, discussions with family and caregivers should be similar to those made regarding "do not resuscitate," assessing the values and goals of the patient.[42] Counselling for ICU caregivers as well as family, including postmortem "debriefings," can be very valuable to help staff deal with end-of-life issues. There are few settings where withdrawal of therapy can so immediately result in death, where patients have intact neurologic function but are on the "bridge to nowhere"; it can be extremely troubling to all involved when ECMO is stopped.

TABLE 85.2 The "RESP" Score for Pre-ECMO Prediction of Survival at 30 Days After Initiation of VV ECMO for Respiratory Failure

PARAMETER	Score

The Mechanics of Extracorporeal Membrane Oxygenation

THE PUMP

The delivery of ECMO includes a centrifugal pump in series with a membrane oxygenator connected by tubing to an inflow and an outflow cannula from the pump to the patient. Convention is to describe the cannulae in relation to the pump: the inflow cannula aspirates venous blood from the patient and the outflow cannula carries arterialized blood from the pump to the patient. Figs. 85.3 and 85.4 illustrate two common ECMO pumps in use today. Fig. 85.3 shows the Maquet Cardiohelp device (Getinge Group, Wayne, NJ) where the pump head and oxygenator are combined into one disposable unit. Fig. 85.4 shows the Thoratec CentriMag pump where the pump head and oxygenator can be disposed separately. Both pumps work in a similar manner with a magnetically driven rotor. Note, the only variable that is adjustable on the pump is the number of revolutions per minute (RPM); the flow generated at a given RPM is dependent on filling (preload) and impedance to ejection (afterload).[43] In the human heart, it has been argued that venous return is the single most important factor in maintaining adequate cardiac output.[44] In a similar way, the most important determinants of flow for a centrifugal pump fed from the patient's central veins and right atrium are the volume status of the venous circulation and internal diameter of the cannula. Also important in VA ECMO is the mean systemic pressure, as the flow from the pump will be reduced by hypertension. While the centrifugal pumps used in ECMO are relatively nontraumatic to red blood cells, there is hemolysis especially at high RPM settings. In order to maximize flow at a low RPM, thereby reducing hemolysis, the goal is to maintain adequate preload and decrease afterload. Use of the largest possible arterial or outflow cannula will also reduce hemolysis but this need must be balanced with the patient's vessel size.

What is less clear physiologically is how much ECMO flow is necessary for adequate tissue perfusion. This is a complex question and the answer can vary depending on the current physiologic state of the patient (e.g., native cardiac function, hyperthermia, hypothermia, sepsis, ischemia).[45] Most centers have settled on a "normal cardiac output" ECMO flow of 2.2 to 2.4 L/min/m^2 as an initial goal, but this may not be possible in a large patient due to cannula size. Using markers of end-organ perfusion (mental status changes, lactate, mixed venous oxygen saturation, liver function

tests, creatinine), the flow goal can be changed as is feasible and necessary.[46] A very important feature of ECMO is that the flow is not necessarily replacing the patient's own cardiac output, either on the right side or the left. With VV ECMO, the circuit may oxygenate only a fraction of the total venous return so that there will still be significant shunt of poorly oxygenated blood through the lungs. With VA ECMO in severe cardiac failure, the circuit may supply the majority of blood flow but as cardiac function improves, native flow may become a significant proportion of total flow. In this case, similar to VV ECMO, the native blood flow through the lungs will dilute the gas exchange benefit provided by the VA ECMO.

The effects of continuous flow rather than physiologic pulsatile flow on the vasculature and organ systems have been studied for short-term CPB runs and long-term durable LVADs, but not well for moderate duration (e.g., days to weeks) as seen in ECMO patients. Changes with durable LVADs include increased aortic valve regurgitation (if it is not opening), histological alterations in the aorta making it stiffer, gastrointestinal mucosal changes associated with increased bleeding and arteriovenous malformations, and acquired von Willebrand disease.[47] Despite this, continuous flow nonpulsatile pumps have replaced pulsatile pumps in all settings of extracorporeal support because of their simplicity, durability, and the reduced trauma to formed elements of the blood; while still being investigated, pulsatile modifications or replacements are not on the clinical horizon. Hemolysis and issues related to coagulation top the list of things to follow closely while on a continuous flow circuit.[48] Lactate dehydrogenase, haptoglobin, bilirubin, and free hemoglobin all remain important laboratory parameters to follow while on ECMO as a way to assess for hemolysis.[49]

THE OXYGENATOR

The membrane oxygenator is constructed to separate gas flow around microtubules of membrane through which the blood is passed, with additional circuitry permitting heat exchange. Traditionally "flow" refers to the flow of blood through the ECMO circuit, and the amount of air-oxygen mixture run through the oxygenator is the "sweep." Oxygenation of the blood is determined by the FiO_2 of the sweep gas mixture, and carbon dioxide removal is determined by the liters per minute of sweep, which is commonly in the range of 1 to 5 L/min depending in part on the patient's metabolic state, size, native lung function, and ventilator settings. Oxygen transfer is very effective at normal blood flows, with post-oxygenator blood samples usually showing a partial pressure of oxygen (pO_2) of more than 300 mm Hg when the sweep is 100% oxygen. As mentioned before, the patient's blood gas values will be the result of a combination of the ECMO blood flow with its carbon dioxide and oxygen content, and the patient's native circulation and gas exchange. Figs. 85.3 and 85.4 show the membrane oxygenator most widely used in North America, the Quadrox made by Getinge (the oxygenator and pump head are one unit with Maquet). With time (days to weeks) the oxygenator becomes less efficient at gas exchange due to build-up of fibrin and micro- or macrothrombi. Need for an increase in FiO_2 or sweep should prompt an evaluation of the pressure drop across the membrane and drawing of a post-oxygenator blood gas.

PULSATILITY WITH VA ECMO

Pulsatility is a term used when describing the arterial waveform both in patients on ECMO and in those with durable LVADs. In the latter case, pulsatility with the cardiac cycle may be related both to LV ejection (i.e., independent of the LVAD) and to the increased filling of the ventricular assist device due to left ventricular contractility. Pulsatility can be detected in this latter case even without aortic valve opening. With VA ECMO the blood filling the ECMO circuit comes from the venous side so any pulsatility is due entirely to left ventricular ejection. When VA ECMO is initiated for cardiac decompensation, there is often very little pulsatility, but as the left ventricle recovers there is gradual recovery of a normal arterial waveform as native left ventricular ejection increases. With VV ECMO, there is normal filling of the left ventricle and arterial pulsatility is not affected.

FLOW AND GAS EXCHANGE PHYSIOLOGY WITH VV ECMO

When VV ECMO is instituted using two separate cannulae as shown in Fig. 85.5, there are two main limitations to its effectiveness. The first limitation is that the patient's native cardiac output may be equal to or even greater than the ECMO flow, which is functionally a large shunt through the lungs. This may lead to inadequate oxygenation despite what appears to be appropriate pump and oxygenator function. The second limitation, due to proximity of the cannulae in the right atrium, is recirculation where some portion of the oxygenated blood being pumped into the patient is aspirated back into the inflow cannula rather than going through the tricuspid valve. This will also result in poor gas exchange.[50,51] Use of the Avalon dual-lumen cannula (Figs. 85.6 and 85.7), where blood is aspirated from superior vena cava and inferior vena cava ports on one lumen and returned through a port positioned (using transesophageal echocardiography [TEE] guidance) such that it flows into the tricuspid valve, is less likely to cause recirculation. The improvement in gas exchange with VV ECMO may result in at least partial relief of pulmonary hypertension, possibly avoiding the need for right ventricular assist (i.e., V-PA or VA ECMO). If oxygenation is not adequately improved due to problems with recirculation or native cardiac output, either additional pulmonary measures such as increasing PEEP and/or prone positioning, or transfusing to a higher hemoglobin can improve oxygen delivery. Addition of a second ECMO circuit is also a possibility.

FLOW AND GAS EXCHANGE PHYSIOLOGY WITH VA ECMO

Peripheral VA ECMO usually is performed with a venous cannula advanced from the femoral vein into the right atrium, and a femoral arterial cannula that ends in the internal iliac artery (Fig. 85.8). Physiology of this arterial flow is complex in that it competes with native left ventricular ejection and also poses an afterload stress to the failing left ventricle.[52,53] A principle of treating the failing heart is

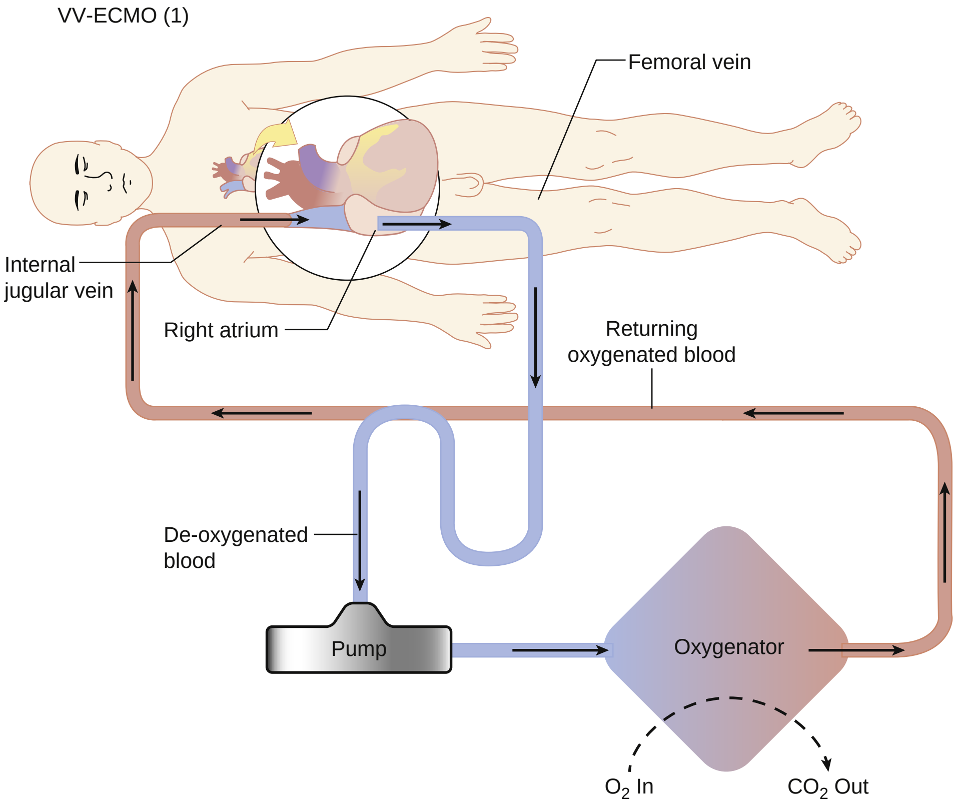

Fig. 85.5 Traditional venovenous extracorporeal membrane oxygenation *(VV ECMO)* circuit with inflow cannula in right femoral vein and outflow cannula in right internal jugular vein.

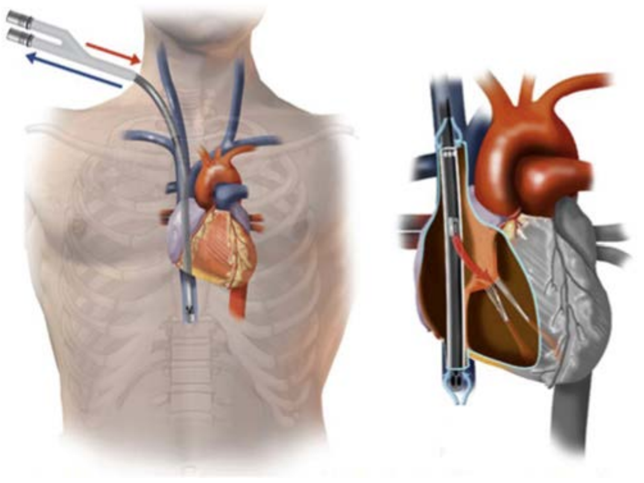

Fig. 85.6 Venovenous extracorporeal membrane oxygenation cannulation with the Avalon cannula, Maquet Inc. The dual-lumen catheter is placed in the right internal jugular vein, with venous blood drawn from the superior and inferior vena cavae (*blue arrow*) into the extracorporeal membrane oxygenation circuit where it is oxygenated and pumped back into the right atrium directed toward the tricuspid valve (*red arrow*). (Courtesy MAQUET Cardiovascular, LLC, Wayne, NJ.)

to reduce wall stress and myocardial oxygen consumption and decrease pulmonary pressures; this is violated with VA ECMO. As discussed, it may be necessary to decompress the left ventricle with either an Impella or a surgically placed left ventricular vent if it is not possible to adequately improve left ventricular function with inotropes or to keep systemic pressures low. Competition with left ventricular ejection means that the ECMO flow from the iliac artery may not reach the aortic arch, leaving the coronary and cerebral vessels hypoxic if there is poor native lung function. The place in the aorta where the ECMO flow meets the native flow (from the left ventricle-aortic valve) is sometimes called the “mixing cloud”; ideally this is as close to the heart as possible. For this reason the right radial artery, reflecting aortic blood flow closest to the heart and to the brain, rather than the left is the sampling site of choice.[54] The phenomenon of poorly oxygenated cerebral and upper body oxygenation but good oxygenation in the lower body is called the “harlequin syndrome” (after an autonomic condition associated with asymmetric upper body sweating and flushing). Solutions to this problem include central cannulation (requiring sternotomy/thoracotomy) where the arterial cannula is in the ascending aorta, or addition of a second cannula in the right atrium to which part of the ECMO outflow is diverted, or VAV ECMO.[55] This runs the risk of recirculation at the atrium, as well as too high a flow diverted away from the aorta and systemic circulation due to the low resistance of the pulmonary circulation. Partial clamping of this cannula to increase resistance will help drive blood to the systemic cannula.

EXTRACORPOREAL MEMBRANE OXYGENATION FOR THE FAILING RIGHT HEART

Clinical circumstances where only the right heart needs mechanical assist are less common than when the left ventricle or both ventricles are failing. Pulmonary hypertension with right ventricular failure in the pre-lung transplant

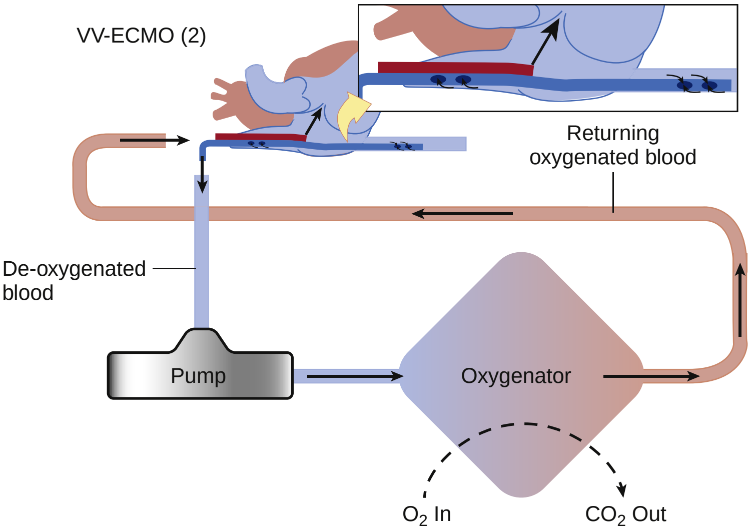

Fig. 85.7 Venovenous extracorporeal membrane oxygenation *(VV ECMO)* circuit using the Avalon cannula (Maquet Inc.).

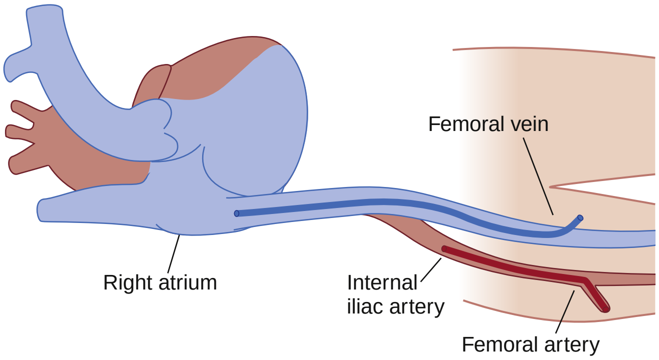

Fig. 85.8 Venoarterial extracorporeal membrane oxygenation circuit with femoral cannulation. The venous cannula *(dark blue)* is advanced to the junction of the inferior vena cava and right atrium, then attached to the pump inflow side of the circuit; the arterial cannula *(red)* is advanced to the iliac artery and attached to the oxygenator/pump outflow side of the circuit.

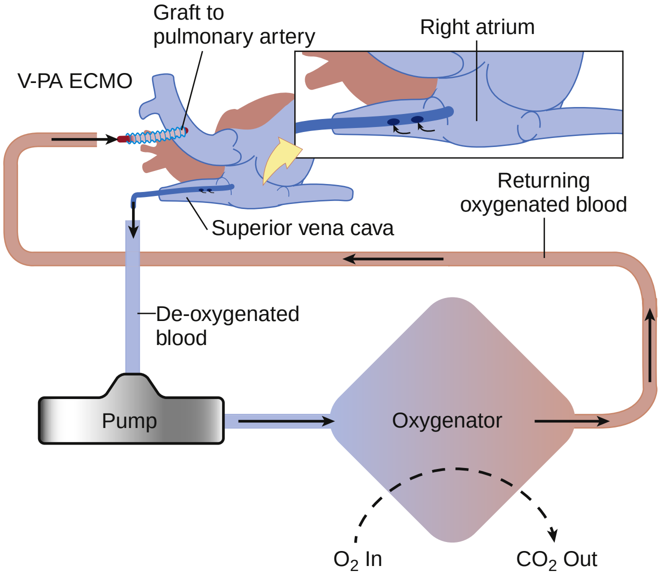

Fig. 85.9 Venous-pulmonary artery extracorporeal membrane oxygenation circuit showing the venous cannula placed through the internal jugular vein to the right atrium, and the arterial cannula placed in a graft which is sewn to the pulmonary artery.

patient, or immediately post-durable LVAD placement where there is right ventricular failure are two examples. It is possible to support the right ventricle alone with V-PA ECMO where the venous cannula is in the right atrium and the “arterial” (outflow) cannula is surgically placed in the pulmonary artery via a graft (Fig. 85.9). If the lungs are intact, then an oxygenator may not be needed and support of the right ventricle can be accomplished by percutaneous devices (TandemHeart or Impella) or with the surgically placed ECMO, or, more correctly, right ventricular assist device (RVAD) circuit without an oxygenator. If there is also respiratory failure, then an oxygenator can be added to the circuit to provide true ECMO. This latter combination for right ventricular failure after LVAD provides a flexible means for managing the RV, lungs, and LV relatively independently.[56]

Vascular Access for Extracorporeal Membrane Oxygenation

Vascular cannulation location and technique vary depending on the type of support needed, the patient’s age, size, and clinical situation, and the need for imaging. Actual placement techniques include percutaneous vessel puncture (Seldinger technique) followed by guidewire, serial dilators, then finally the cannula. Alternatively, surgical cutdown and direct exposure can be used for peripheral vessels. Finally, surgical access to the right atrium, pulmonary artery, and ascending aorta requires sternotomy/thoracotomy. For percutaneous access there can be little doubt that ultrasound is a very valuable aid. Although there is little science to support this contention specifically for ECMO, in other settings there is compelling evidence.[57,58]

In order to verify placement of the venous cannula appropriately in the right atrium or at the junctions of the superior and inferior vena cavae with the right atrium, TEE is very helpful; similarly during placement of guidewires in peripheral vessels the use of TEE to verify wires in the aorta or the right atrium is also very helpful. Finally, radiographic imaging may be used for guiding the wire used for right internal jugular (RIJ) vein placement with a dual-lumen catheter (AVALON) (see later), followed by TEE imaging to verify correct cannula placement. Vascular cannulation, especially arterial, requires heparinization during cannula placement and generally also requires two operators, for either percutaneous access (one person to handle guidewire, dilators, and intermittent vascular occlusion) or for cutdown (surgical assistance in addition to handling wire and dilators).

CANNULATION FOR VV ECMO

In the original descriptions of VV ECMO in adults, two cannulae were used: one usually inserted in the right femoral vein and advanced to the junction between the inferior vena cava and the right atrium, and the other inserted in the RIJ vein and advanced through the superior vena cava into the right atrium (see Fig. 85.5). The largest possible cannulae are used to maximize flow (see later). When the cannulation of the IJV is technically not possible, an alternative configuration of VV ECMO support involves bilateral femoral cannulation. The tip of the drainage venous cannula is placed in the inferior vena cava while the tip of the outflow cannula is positioned into the right atrium. Either two-cannula technique presents a major drawback in terms of recirculation, where some portion of the oxygenated blood returned to the right atrium is reaspirated back into the inflow cannula.

The Avalon ELITE is a dual-lumen cannula used in contemporary VV ECMO and many centers insert this catheter as the first choice if possible. With this cannula designed for RIJ placement, one lumen is used for inflow to the ECMO circuit; this lumen is designed to reside such that ports for aspiration of blood are in both the superior and vena cavae but not the right atrium. The second lumen where the pump outflow is directed is designed to be positioned in the right atrium aimed at the tricuspid valve (see Fig. 85.6). By use of inflow ports in the vena cavae and outflow in the right atrium directed at the tricuspid valve, blood recirculation is minimized. Use of echocardiography to place the cannula is important to be sure the inflow and outflow ports are in the correct position. TEE is especially useful in identifying the direction of the outflow jet of blood toward the tricuspid valve. In addition to the advantage of a single vascular access and minimal recirculation, the Avalon ELITE catheter improves patient comfort and facilitates mobilization and rehabilitation. It may also decrease the infectious risk associated with groin cannulation. The main limitation of this cannula is the maximum internal diameter achievable for pump inflow, as this is the main determinant of the flow rate.

CANNULATION FOR VA ECMO

The objective of VA ECMO is to provide oxygenated blood into systemic circulation so cannulation of a large artery for the outflow cannula is required. The femoral arteries are usually the first choice, and only in particular conditions (e.g., burns, open wounds, significant peripheral vascular disease) is the subclavian or axillary artery used. Vascular cannulation for peripheral VA ECMO is therefore most commonly done using a venous cannula in the femoral vein advanced to the inferior vena cava/right atrium junction, and an arterial cannula entering the femoral artery with the tip residing in the common iliac artery (Fig. 85.8). As in VV ECMO, the maximum flow achievable is mostly determined by the internal diameter and length of the venous cannula. Placement of the femoral arterial cannula, as with the venous cannula, can be done using the Seldinger technique and serial dilators, or surgical cutdown. Imaging is not required; the venous cannula is placed by the inserter estimating the position of the inferior vena cava/right atrium junction, with possible adjustment in position if needed at a later time. Surgical cutdown is required for accessing the subclavian or axillary artery.

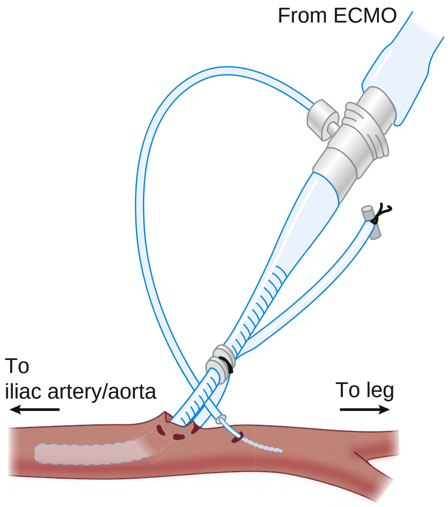

Fig. 85.10 Illustration of a "distal perfusion cannula" in the femoral artery. The extracorporeal membrane oxygenation (ECMO) arterial cannula is placed in the artery and advanced to the internal iliac artery; the distal perfusion cannula is placed distal to the arterial ECMO cannula, aiming down the leg to provide additional perfusion.

In an attempt to reduce the incidence of distal limb ischemia in the cannulated leg, small catheters (commonly referred to as distal perfusion catheters) can be placed distal to the ECMO arterial cannula, aiming down the leg (Fig. 85.10). Different parts of the distal limb arterial tree can be used as cannulation sites; the femoral artery is most often used but the superficial femoral artery or posterior tibial artery have also been described. Another possible approach to limit distal limb ischemia is to sew a synthetic graft on the femoral artery, and place the cannula in the graft rather than the vessel itself. This approach is always used for subclavian/axillary cannulation. In some centers the femoral artery and vein on the same side are cannulated; in others one cannula is placed in each extremity in order to avoid both reduced arterial perfusion and increased venous obstruction to the same extremity.

The subclavian/axillary artery cannulation for VA ECMO has both advantages and drawbacks when compared to the femoral site. The subclavian artery is rarely affected by atherosclerotic lesions compared to the femoral artery; the presence of a rich collateral flow may reduce the risk of distal extremity ischemia, bacterial contamination is less likely in this anatomic region, and it provides a systemic antegrade perfusion into the distal aortic arch (more proximal than the common iliac). The drawbacks include a potentially challenging surgical dissection in obese patients or in the presence of chest wall edema; the vessel is smaller than the femoral artery, and the limited reports for its use suggest an increased risk of hyperperfusion (rather than hypoperfusion) to the extremity.[59] It is not used in acute emergent cannulations (e.g., unstable cardiogenic shock or cardiac arrest) as it is time-consuming. With axillary artery cannulation, the venous cannula is usually placed in the RIJ to obtain the potential benefit of patient mobility.

Direct cardiac and aortic cannulation for VA ECMO is usually used for patients who cannot come off CPB in the operating room, using the CPB cannulas (central ECMO). The short, large-bore venous cannula permits excellent venous drainage. As oxygenated blood is returned to the ascending aorta, there is less concern for upper body hypoxemia. Other circumstances where central VA ECMO may be used include failure to obtain adequate flow from peripheral cannulation due to vessel size or disease, inadequate improvement in oxygenation (usually upper body), or vascular complications from peripheral VA ECMO. Central cannulation may also facilitate mobilization (e.g., out of bed) provided there is chest wall stability.

CANNULATION FOR VPA ECMO

Where there is right ventricular dysfunction or failure but intact left ventricular function, it would be ideal to avoid peripheral arterial cannulation (i.e., VA ECMO). If the lungs function adequately, a temporary RVAD could be used (e.g., Impella). If lung assist in addition to right ventricular assist is needed, then two options are (1) VPA ECMO using a graft placed surgically on the pulmonary artery for outflow and either a femoral or RIJ venous cannula, or (2) use of a Protek Duo (Cardiac Assist, Inc., Pittsburgh, PA) dual-lumen cannula similar to the Avalon but designed to have the tip reside in the pulmonary artery rather than the inferior vena cava. This cannula is placed via the RIJ with inflow ports in the right atrium and outflow ports in the pulmonary artery. It can provide both oxygenation and cardiac output for the pulmonary circulation but not require a systemic (arterial) cannula. Although there is less experience with the Protek Duo dual-lumen cannula than with the Avalon, it appears to be promising.[60]

ALTERNATIVE CANNULATION STRATEGIES

The cannulation strategy may not be fixed for the duration of the ECMO support; patient physiology or clinical condition and needs may change over time and modifications in ECMO configuration may occasionally be necessary. Conversion from the initial ECMO strategy to a different modality should always be strongly considered if the patient's perfusion is inadequate, other goals of therapy are not being met, or if complications are arising as a result of the cannulation strategy, for example upper extremity hypoxemia with femoral VA ECMO[61] or left ventricle distension with VAECMO.

Conversion from VV to VA or from VA to VV ECMO, or the use of "hybrid" modes, may be desirable or necessary. Patients on VV ECMO can have hemodynamic deterioration (secondary to right, left, or bi–ventricular failure) and require cardiocirculatory support. This can be achieved by the addition of an arterial perfusion cannula to the circuit. This ECMO configuration (also known as veno–arterial–venous [VAV] ECMO) provides circulatory support through an arterial cannula introduced via the femoral or subclavian artery and is referred to as a hybrid approach.[62] In situations where femoral VA ECMO does not provide sufficient oxygenated blood to the upper body (harlequin syndrome or north/south syndrome), an extra outflow cannula can be introduced to the right atrium via the RIJ, directing oxygenated blood into the pulmonary circulation (VAV ECMO hybrid approach).[63] Alternatively, the femoral arterial cannula can be converted to a central (proximal aortic) position, requiring sternotomy or thoracotomy. When there is left ventricular distension with VA ECMO that cannot be overcome with inotropic drugs, then surgical placement of a left-sided inflow vent (usually in the left atrium or pulmonary vein) or insertion of an Impella may be necessary. Placement of additional cannulae of any kind must be approached with caution and the cannula flow monitored. Bleeding and clotting complications are compounded by use of additional cannulae.

Monitoring on Extracorporeal Membrane Oxygenation

PUMP PRESSURES AND FLOWS

Understanding pressures and flows in the circuit is key to the management of an ECMO patient. The Maquet Cardiohelp device has built-in pressure transducers such that it measures the incoming pressure to the pump (the venous pressure), the pressure after the pump but before the oxygenator, and finally the pressure after the oxygenator (the outflow pressure). It also has a flow probe on the outflow cannula and a monitoring probe for air on the inflow cannula. In order to generate flow, the pump creates a negative pressure on the venous side, and this pressure is displayed on the console. As this pressure becomes more negative, concern arises regarding the volume status of the patient, or a cannula issue (e.g., obstruction, position). For the same flow a smaller cannula will require a greater negative pressure. Greater negative pressures usually precede the phenomenon of venous line "chatter" where flow is intermittently reduced or stopped when the inflow ports (in the superior vena cava and/or right atrium) are sucked against the venous wall due to inadequate volume status of the patient.

The pressure change across the oxygenator is used to indicate the possibility of obstruction due to accumulation of fibrin or clot. Outflow cannula pressure, also displayed, can be elevated by cannula obstruction or high arterial pressure in the patient. Smaller cannulae require higher pressures to generate flow than larger ones. The Maquet Cardiohelp device also has a sampling port on the outflow cannula (post oxygenator) to allow blood gas analysis in the assessment of membrane function; declining pO_2 or rising carbon dioxide partial pressure (pCO_2) indicate a need to change the oxygenator. There is no venous side sampling port; this may be useful on VV ECMO when there is suspicion of recirculation as described previously, but an access point pre-pump is a potential source for air entrainment.

Flow probes can be applied to the branches of outflow cannulae connected to the circuit if these are employed. For example, a probe can be attached to the distal perfusion cannula used in peripheral VA ECMO or to the left ventricular vent in the centrally cannulated patient. A flow that drops abruptly may indicate occlusion of the line possibly from fibrin/thrombus formation.

INTRAVASCULAR PRESSURES

The arterial catheter offering both continuous blood pressure monitoring and sampling for blood gas analysis is an essential monitor in this patient population. As previously mentioned, all current forms of mechanical circulatory support (except intraaortic balloon pumps) provide continuous flow. In the patient on VA ECMO, the arterial line provides real-time information regarding the relative contribution of the native heart (pulsatile) versus the ECMO pump (nonpulsatile). Blood pressure cuffs (manual or automatic) are not able to provide this type of continuous monitoring and in the absence of pulsatility may not be able to measure the pressure at all. In the VA ECMO patient, the location of the arterial catheter is also important as mentioned; blood gas samples from left upper extremity catheters may not reflect the blood perfusing the coronaries and the brain, depending on the location of the "mixing cloud."

A central venous catheter provides access to administer vasoactive and inotropic drugs, and while the presence of a large cannula near or in the right atrium from which the ECMO pump is aspirating blood likely affects the pressure measurement, it can be a useful trend to monitor especially during weaning of flow. Although use of the pulmonary artery catheter in settings other than severe heart failure or cardiac surgery has greatly declined, it provides very useful information in the patient on VA ECMO. As discussed previously, a problem with VA ECMO is left ventricular distension due to the afterload stress; elevated or rising pulmonary artery pressure can be the first indication of this phenomenon, preceding pulmonary edema or even pulmonary hemorrhage. A rising mean pulmonary artery pressure may initiate a discussion regarding treatment with inotropic medications or placement of an Impella device, and be used to monitor the effectiveness of such treatment. During weaning trials when the ECMO pump flow is progressively reduced, the pulmonary artery catheter provides pressures on both sides of the heart and information about biventricular function.

TISSUE OXIMETRY

Tissue oximetry has been used for many years in the cardiac operating room to assess the adequacy of cerebral perfusion. Some ECMO centers are now using this technology to assess both cerebral oxygenation (in the sedated patient) as well as distal extremity perfusion where there is vessel cannulation.[64] Tissue oximetry applied to the lower extremities may alert the provider of a mismatch between the cannulated extremity and the one that is not. This information, along with clinical assessment (physical state of the extremity and pulses) and flow probes applied to the circuit can be used to guide intentional changes in flow or cannula reposition/relocation. Decreasing the cannulated extremity perfusion can sometimes be necessary if there is edema or compartment syndrome.

Anticoagulation

There is continuous contact between the foreign surfaces of the circuit and the patient's blood while on ECMO. Foreign surfaces are intrinsically thrombogenic, placing the circuit components at an increased risk for thrombosis and the patient at risk for embolic complications as well as reduced pump effectiveness. Both Maquet and Thoratec (Thoratec Corp., Pleasanton, CA) have tried to at least partly address this issue by coating the blood-contacting surfaces of the circuit components with proprietary heparin or heparin-albumin bonding processes. In some instances it is possible to run ECMO without anticoagulation at all or using low levels of anticoagulation, but this is not well studied.[65,66]

The membrane oxygenator and distal perfusion tubing used in femoral arterial cannulation are commonly reported sites for clot formation. In order to prevent thrombosis, the standard practice in North America is to administer antithrombotic therapy to a target below the levels used for CPB. The goal is to maintain the circuit with minimal thrombotic risk to the circuit and minimal hemorrhagic risk to the patient.[67] Anticoagulation targets may be altered by the absence of circuit coating, the flow rate (higher target for lower flows), and patient-specific factors such as thrombocytopenia or other coagulation disorders.

Unfractionated heparin (UFH) is the most commonly used anticoagulant for ECMO. Heparin works via antithrombin 3 (AT3); the heparin-AT3 complex then inhibits thrombin and factor Xa.[68] Patients usually receive an initial UFH bolus of 50 to 100 units/kg at the time of cannulation. Dosing of UFH and measured anticoagulation status are institution specific. Problems with the use of UFH include its relative unpredictable bioavailability, the necessity for maintaining AT3 levels, and the occurrence of heparin-induced thrombocytopenia with thrombosis (HITT).[67,69] If the AT3 concentration in plasma is low, coagulation can occur even when large doses of heparin are given. The level of AT3 should be monitored, especially if there is an increasing need for heparin dose to achieve the desired anticoagulation. A low AT3 level can be treated by giving fresh frozen plasma or recombinant AT3.

Therapeutic Monitoring of Unfractionated Heparin (Table 85.4)

ACTIVATED CLOTTING TIME

The activated clotting time (ACT) remains the most commonly utilized test for ECMO to guide UFH dosage, partly due to its being a point-of-care (POC) whole-blood test that

TABLE 85.4 Anticoagulation Strategies

Drug	Pro	Absolute/Relative Contraindications
No anticoagulation	Avoids anticoagulation in high-risk patients (hemorrhagic CVA, postoperative bleeding, etc.)	High risk for thrombus/embolism/short circuit life span
Unfractionated heparin	Most frequently used	HITT
Low-molecular-weight heparin	Infrequently used	Very dependent on renal function and patient weight, HITT
Argatroban	No concern for HITT	Hepatically cleared
Bivalirudin	No concern for HITT, short half-life	Renally cleared
Heparin bonded circuits	Decreases fibrin coating of circuits	HITT

HITT, Heparin-induced thrombocytopenia and thrombosis.

provides immediate results.[70] Results of the ACT may be affected by factors other than UFH including anemia, hypofibrinogenemia, thrombocytopenia and coagulation factor deficiencies, hypothermia, and hemodilution. The UFH infusion is titrated to maintain the ACT at institution-specific levels, usually 1.5 times normal (180-220 s).[18]

ACTIVATED PARTIAL THROMBOPLASTIN TIME

The activated partial thromboplastin time (aPTT) is a laboratory standardized test used in adults where moderate doses of UFH are administered, and many adult ECMO programs use the aPTT instead of the ACT. The aPTT appears to more accurately reflect heparin anticoagulation in the critical care setting.[71]

Although POC devices are available, in most institutions the aPTT test is performed in the hospital laboratory with the attendant delay in obtaining results. Point-of-care devices which measure the aPTT are available, but these tests are done on whole blood samples and may not be as reliable as laboratory run tests. The laboratory aPTT may be affected by factors other than heparin effect such as factor deficiencies or presence of inhibitors. If the patient has a high platelet or white cell count, or is hypercoagulable, a large amount of heparin may be required to maintain the target aPTT. If the patient is thrombocytopenic, in renal failure, or has circulating fibrin split products, a reduced aPTT target may be appropriate.

ANTI-FACTOR XA (“HEPARIN LEVEL”)

Some institutions use the anti-factor Xa (anti-Xa) assay as the gold standard test to monitor therapeutic UFH dosing.[72] The anti-Xa assay is not a measure of UFH concentration, but rather a measure of UFH effect, based on the ability of the UFH-AT3 complex to inhibit factor Xa.[68] In contrast to the ACT and aPTT, the anti-Xa assay is specific to the anticoagulant effect of UFH and is not influenced by coagulopathy, thrombocytopenia, or dilution. Studies in this patient population have shown poor correlation of anti-Xa assay to ACT, suggesting the anti-Xa test to be preferable.[73] In addition, the anti-Xa activity is associated with better accuracy and reproducibility than the aPTT in many clinical settings.[74]

HEPARIN-INDUCED THROMBOCYTOPENIA

Heparin induced thrombocytopenia (HIT or HITT) is a relatively uncommon but severe complication of UFH therapy. Diagnosis may be challenging with patients on ECMO, as thrombocytopenia from various origins (multiorgan dysfunction, sepsis, platelet activation and consumption by the ECMO circuit, bleeding, hemodilution) is common. Two types of HITT are described: type I is relatively benign, of nonimmune origin, and occurs early without thrombotic complications. It usually spontaneously resolves despite continued treatment with heparin; type II (HITT) is life threatening, of immune origin, and late onset. This syndrome leads to venous and/or arterial thrombosis.[75]

HITT treatment consists of stopping the UFH infusion and any contact with any form of heparin, avoiding platelet transfusions, and administering an alternative anticoagulant treatment such as one of the direct thrombin inhibitors, argatroban or bivalirudin. Argatroban is hepatically cleared whereas bivalirudin has a component of renal elimination; both drugs must be carefully dose-adjusted and monitored in critically ill patients. The Maquet circuit is always heparin-bonded; it is possible to have non-heparin bonded circuitry using the Thoratec CentriMag system. As the effect of heparin-bonded circuitry on the development or maintenance of HITT is not well understood, if HITT is diagnosed there should be an effort to change to a non-heparin bonded circuit.[76]

Weaning from Extracorporeal Membrane Oxygenation

WEANING FROM VA ECMO

Weaning from VA ECMO is both an art and a science as every patient is different, and both pulmonary and cardiac weaning may be required. Many of the principles used in the cardiac operating room to separate a patient from CPB apply to the patient on VA ECMO. “Ramp” trials for VA ECMO patients where the ECMO support is reduced in a graded fashion while monitoring blood pressure, filling pressures, oxygenation, and often continuous echocardiography, are part of the management of the ECMO patient in the ICU.[56] The pulsatility of the arterial waveform and how it is affected when the ECMO flow is reduced is also important. The desired response to a ramp trial is for the patient to maintain stable blood pressure and pulsatility on minimal inotropic and vasopressor support, with no significant increase in filling pressures, and preserved ventricular function by echocardiographic assessment. Another important consideration is resolution of pulmonary congestion or edema before a ramp trial is performed. In general, once the patient is ready for weaning, there will be good pulsatility indicating the native cardiac output is perfusing the ascending aorta and great vessels; the blood gas from the right radial artery will reflect the native lung function. It may be desirable to reduce the FiO_2 of the sweep, and reduce the sweep itself to confirm that the patient can oxygenate and ventilate adequately with their own lungs. This will require arterial blood gas analysis. Appropriate anticoagulation is important before the ramp trials; often a small bolus dose of heparin (e.g., 1000 units) is given prior to the trial, and as a general rule bedside ramp trials for VA ECMO in the ICU do not decrease the blood flow below 2 L/min. It is important to keep in mind that other cannulae that may come off the main ECMO circuit will also show a decrease in flow during ramp trials (distal perfusion cannulae or left ventricular vents). Providers should be mindful of this when managing patients with high-risk extremities or threatened limbs (large arterial cannulae and/or technical issues related to the distal perfusion cannula itself). Once it is clear that the ramp trial is successful, patients can then be taken to the operating room for decannulation where they are usually monitored with TEE and a pre-decannulation ramp trial is repeated. In some institutions decannulation can be performed in the bedside in the ICU with an operating room-like setup for surgical repair of the artery.

Weaning from VPA ECMO is similar to weaning from VA ECMO but the focus is on the right heart rather than the left heart, and with at least equal attention to the ability of the patient's own lungs to adequately perform gas exchange.

WEANING FROM VV ECMO

VV ECMO ramp trials are often easier to perform as most of the information regarding the ability of the patient's lungs to oxygenate and ventilate can be learned without a change in circuit flow. The purpose of the VV ECMO circuit is to perform gas exchange, but unlike VA ECMO the pump function provides no cardiac support; weaning trials therefore only need to be performed with changes in gas delivery across the membrane. Decreases in FiO_2 of the sweep to reduce oxygenation support, and decreases in sweep itself across the membrane to reduce "ventilation" (CO_2 removal) are all that is required to assess the adequacy of native lung function. Stopping the flow of oxygen/air across the membrane entirely may be performed as a last step prior to decannulation. This is called a "cap" trial whereby a cap is placed over the gas delivery inlet of the membrane valve itself. However, this process may damage the oxygenator, and if the trial is unsuccessful, may lead to a need to replace it. As a general principle, the sweep should not be reduced below 0.8 L/min for anything but a brief (few minutes) time. Venous ECMO cannulae can usually be removed in the ICU without the need for vascular repair.

WEANING THE PATIENT WITH SEPARATE RVAD, LVAD, AND ECMO

Some patients with biventricular failure and pulmonary edema may have cardiopulmonary support in a configuration of CentriMag LVAD, a CentriMag RVAD, and an oxygenator connected to the RVAD circuit. This cannulation strategy provides separate biventricular support with the added benefit of an oxygenator in a VV ECMO configuration (i.e., LVAD plus VPA ECMO). It provides the ability to separately assess native lung function, right heart function, and left heart function during ramp trials. The VV ECMO weaning trial can then be performed as described, without a change in LVAD or RVAD blood flow. Reduction in FiO_2 of the sweep and in the sweep itself are monitored with arterial blood gases, with the ability to remove the oxygenator but remain with biventricular support. The RVAD and LVAD can then be weaned separately as determined by the patient's native right- and left-heart function.

Complications of Extracorporeal Membrane Oxygenation

It should not be surprising that there are many complications associated with all types of ECMO. These complications have been the subject of recent systematic reviews both for VA ECMO and for VV ECMO and are also described in the annual reports from ELSO. There is less experience with VPA and VAV ECMO configurations but many of the same issues exist with these more complex circuits. Complications of vascular cannulation, bleeding, or clotting from excessive or inadequate anticoagulation, neurologic injury (i.e., intracerebral bleed) usually related to coagulation management, and infection all occur with a significant incidence. With VA ECMO the majority of vascular complications are arterial; overall vascular complications with VV ECMO, especially the double-lumen Avalon, are less common. Renal injury occurring prior to initiation of ECMO or during an ECMO run is associated with a worse outcome.[77]

Vaquer and associates[78] performed a systematic review and meta-analysis, selecting 12 studies from 2000 through 2015, including 1042 patients who underwent VV ECMO for ARDS. The mean hospital mortality in these studies was 38%, with a mean of 7% mortality due to complications. They found 40% of patients experienced medical complications, the most common of which was some kind of bleeding (29%). Intracerebral bleeding occurred in 5%. The 2016 ELSO report suggests a similar incidence of bleeding looking at adult ECMO for all respiratory indications. The ELSO report describes an incidence of 10% cannula infections with Vaquer and associates[78] finding an incidence of all infections of 17%. The ELSO report does not indicate the mortality attributable to complications, but does give overall mortality of respiratory (VV) ECMO as 38% with 42% hospital mortality.[18]

For VA ECMO, the majority of which is femoral, the overall incidence of complications related to the ECMO itself is greater than for VV ECMO. This is illustrated in the 2016 ELSO report, and two recent independent reports—one single center and one meta-analysis. In the ELSO report of all cardiac ECMO in adults, the overall incidence of bleeding is 42% rather than 32% for VV ECMO. Infectious complications are comparable, but renal failure and hyperbilirubinemia are both greater. In a meta-analysis of 1866 patients who received VA ECMO for cardiac arrest or cardiogenic shock between 2005 and 2012, Cheng and associates[35] found an incidence of major bleeding complications of 40% as well as a similar incidence of needing re-thoracotomy if central ECMO was used after cardiotomy. The incidence of significant infection was 30% overall. Most strikingly the incidence of acute kidney injury was 55%, with 46% needing dialysis. They also found an incidence of lower extremity ischemia of 17%, compartment syndrome requiring fasciotomy of 10%, and amputation of 5%. They did not report mortality attributable to the ECMO. In a single-center report by Kaushal and associates,[79] findings associated with hospital mortality included increasing age, the indication for ECMO being cardiac arrest, prolonged ECMO run, need for pre-ECMO dialysis (but not if initiated during ECMO), and limb ischemia.

PERIPHERAL EXTREMITY ISCHEMIA

As indicated previously, limb ischemia, compartment syndrome requiring fasciotomy, and amputation are significant risks of peripheral cannulation for VA ECMO. Approaches to reducing this complication include careful selection of cannula size, meticulous technique in cannula insertion to prevent vessel injury, and interventions to improve flow to the distal extremity such as placement of a distal perfusion cannula or use of an arterial graft where the cannula resides, rather than the vessel itself. Compartment syndrome can be caused by a mismatch in venous outflow to the arterial inflow, which could potentially be avoided by placing the venous and arterial cannulae in different extremities. Other than use of these measures, attentive monitoring of the cannulated extremity for pulses, edema, pain, tissue tension, and temperature, and early intervention if there are ischemic changes, are essential. As mentioned, some centers use oximetry sensors to compare cannulated and noncannulated extremities.

Hyperperfusion is a less common complication, usually associated with an arterial graft to either a femoral or axillary artery, which then provides the extremity with excessive perfusion leading to hyperemia, patient discomfort, and potentially, compartment syndrome. Chameogeorgakis and associates[59] report that hyperperfusion syndrome occurs in 20% of patients when the axillary artery is used (with the cannula residing in an end-to-side graft to the artery), and 20% of these patients will go on to develop compartment syndrome. This is a reason why the axillary artery is not a vessel of first choice for VA ECMO. We have also seen this in a lower extremity in a small female patient who had an arterial graft due to small artery size, where the venous cannula was in the femoral vein on the same side.

A number of reports have addressed the effectiveness of distal perfusion catheters[80,81] and arterial grafts rather than vessel cannulation[82,83]; while these approaches reduce ischemic complications they do not eliminate them. Vigilance on the part of the care team and early intervention to change cannulation strategy are essential to prevent loss of the limb.

The Anesthesiologist's Role in Extracorporeal Membrane Oxygenation

In many institutions, all ECMO cannulation, management, and decannulation is led by cardiac or thoracic surgeons. In others, respiratory ECMO is managed by a medical ICU team, even when the cannulation is performed by a surgeon. ECMO management in the ICU can involve cardiologists in patients needing cardiac support, pulmonary physicians in those needing only respiratory support, and critical care physicians of all backgrounds in all patients on ECMO. A critical care anesthesiologist who is also cardiac trained is an ideal participant in the management of these patients as many aspects of ECMO are related to CPB. In some institutions nonsurgical members of the critical care team may be involved in the cannulation and initiation of ECMO as well as its ongoing management. The concept of an ECMO team has been described by two of the authors of this chapter, suggesting that outcomes of ECMO can be significantly improved with the strong engagement of cardiac anesthesiologists and critical care anesthesiologists.[84] This may be particularly important in "ECMO to go" where a team from the ECMO center travels to an outside hospital to initiate and then manage ECMO as well as other life-support modalities during transfer. The European experience indicates a stronger role for anesthesiologists in this process than in the United States.[85] Management of patients needing what is essentially a surgical intervention for urgent cardiorespiratory support is very much part of the practice of cardiothoracic anesthesiology, as is the invaluable intraoperative guidance provided by TEE evaluation and monitoring of not only cardiac function, but placement, advancement, and correct positioning of cannulae.[86] Similarly, during decannulation from cardiac ECMO, echocardiographic evaluation of the heart is essential during and after support has been removed.

Acknowledgment

The editors and publisher would like to thank Drs. Zaccaria Ricci, Stefano Romagnoli, and Claudio Ronco for contributing a chapter on this topic in the prior edition of this work. It has served as the foundation for the current chapter.

Cardiopulmonary Resuscitation and Advanced Cardiac Life Support

YAFEN LIANG, ALA NOZARI, AVINASH B. KUMAR, and
STEN RUBERTSSON

KEY POINTS

- Cardiac arrest is a major public health issue worldwide. Despite significant advances in resuscitation science, survival rates remain considerably low. Improvement of patient survival and neurologic outcome relies on the development and implementation of vigorous and evidence-based resuscitation guidelines involving basic life support (BLS), advanced cardiovascular life support, and post–cardiac arrest care.
- In cardiac arrests without hypoxic causes, oxygen content in the lungs at the time of cardiac arrest is usually sufficient for maintaining acceptable arterial oxygen content during the first several minutes of cardiopulmonary resuscitation (CPR). Blood flow rather than arterial oxygen content is the limiting factor for oxygen delivery to coronary, cerebral, and systemic circulation during CPR. Thus rescue breaths are less important than initiating effective chest compressions as soon as possible after sudden cardiac arrest (SCA).
- The mechanism through which chest compressions generate blood flow can be explained by the thoracic or cardiac pump theories. The provision of uninterrupted, high-quality chest compressions after SCA is associated with better survival and neurologic outcomes than delaying chest compressions for airway intervention in both adult and pediatric patients. Circulation, airway, breathing has replaced airway, breathing, circulation.
- A single resuscitative shock should be delivered at the earliest possible opportunity after the recognition of cardiac arrest, followed immediately by the resumption of chest compressions without postshock cardiac rhythm analysis. Outcome studies have failed to demonstrate the benefit of a period of chest compressions before shock or for a series of stacked shocks.
- Vasopressor medications during resuscitation have been de-emphasized in deference to providing uninterrupted, high-quality chest compressions. Standard-dose epinephrine (1 mg every 3-5 minutes) is recommended for patients in cardiac arrest. Vasopressin offers no advantage as a substitute for epinephrine in cardiac arrest and has been removed from the adult cardiac arrest algorithm. Steroids combined with a vasopressor bundle or cocktail of epinephrine and vasopressin improved return of spontaneous circulation (ROSC) compared with the use of placebo and epinephrine alone in out-of-hospital cardiac arrest.
- Continuous-flow left ventricular assist devices result in an unconventional, unique physiologic state of hemodynamically stable pulseless electric activity. Assessment of adequate tissue perfusion is the most important factor in determining the need for circulatory assistance such as chest compressions. Total artificial hearts (TAHs) are refractory to chest compressions, antiarrhythmic drugs, and electric therapy. Vasopressor medications are contraindicated because they increase afterload, result in complete hemodynamic collapse with pulmonary edema, and worsen TAH function.
- In consideration of opioid overdose epidemiology, patients with known or suspected opioid addiction who are in cardiac or respiratory arrest should receive intravenous, intramuscular, or intranasal naloxone in addition to standard BLS care.
- For nonshockable rhythms, the essential step will be early detection and correction of potentially reversible underlying causes. Ultrasound technology is used to assess the etiology and the management of these patients, as well as to predict the possibility of ROSC and to justify the termination of resuscitative efforts. However, utilization of this technique should not interfere with other resuscitation efforts such as chest compressions.
- Asphyxiation is a much more common cause of cardiac arrest in infants and children than the primary cardiac event, and airway management and ventilation are therefore more important during the resuscitation of children. However, in order to facilitate training, retention, and implementation of resuscitation guidelines, the pediatric resuscitation guidelines follow similar principles as adult guidelines.

- Targeted temperature management (TTM) applied to comatose survivors of out-of-hospital cardiac arrests has significantly improved the neurologic recovery in those surviving to hospital discharge. A target temperature between 32°C and 36°C is recommended for at least 24 hours, and normothermia (to treat fever) should be maintained beyond this window. Prognostication should not occur until 72 hours after ROSC or, if TTM is provided, 72 hours after completion of TTM.
- Most deaths after SCA in both adults and children typically occur within the first 24 hours. Coordinated postresuscitation care involving access to coronary catheterization capabilities and intensive care management that includes TTM represents the best chance survivors of SCA have for optimal neurologic and cardiac recovery.
- New technologies such as individualized CPR, extracorporeal CPR, controlled automated reperfusion of the whole body (CARL), and emergency preservation for delayed resuscitation may offer opportunities for patients suffering from cardiac arrest.

Sudden Cardiac Arrest and Cardiopulmonary Resuscitation

BRIEF HISTORY AND PHYSIOLOGIC CONSIDERATIONS

Cardiac arrest is a major public health issue, with more than 500,000 deaths per year in the United States.[1-3] Seventy percent of out-of-hospital cardiac arrests (OHCAs) occur at home, and approximately 50% are unwitnessed. Despite significant advances in resuscitation science, survival rates remain considerably low for both OHCA and in-hospital cardiac arrest (IHCA). Only 10.4% of adult patients with nontraumatic cardiac arrest who receive resuscitative efforts from emergency medical services (EMS) survive to hospital discharge.[4] IHCA has a better outcome, with 22.3% to 25.5% of adults surviving to hospital discharge.[5] Statistics for Europe are similar, with OHCA as one of the leading causes of death in Europe and an overall survival rate of 2.6% to 10.7%.[6-8]

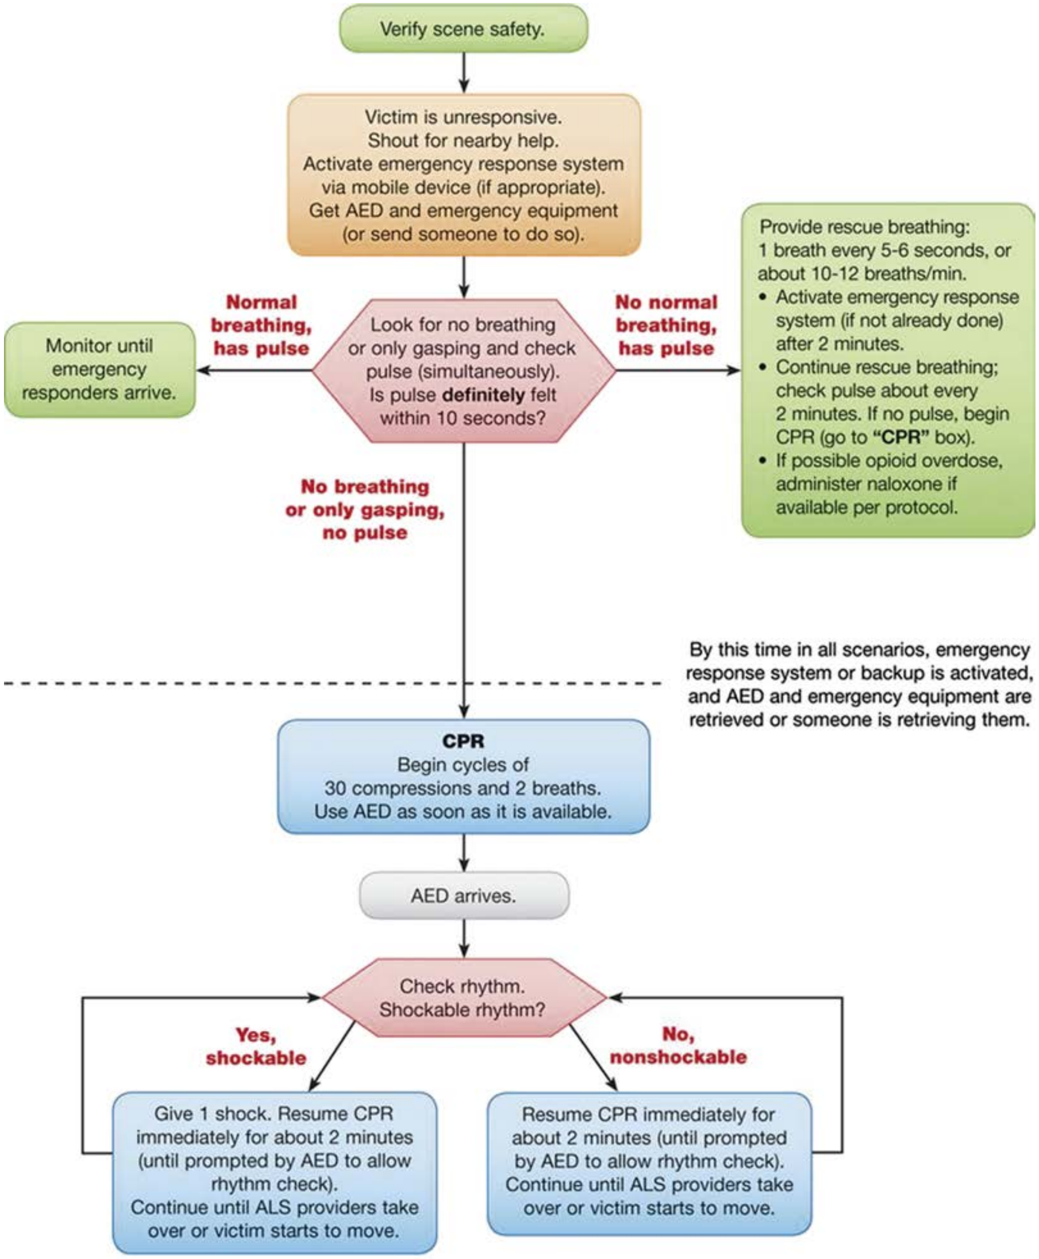
Sudden cardiac arrest (SCA) is a complex and dynamic process. Forward systemic arterial blood flow continues after cardiac arrest until the pressure gradient between the aorta and right heart reaches equilibrium. A similar process occurs with forward pulmonary blood flow between the pulmonary artery and the left atrium. As the arteriovenous pressure gradient diminishes, the left heart filling is decreased, right heart filling is increased, and the venous capacitance vessels become increasingly distended. When the arterial and venous pressures reach equilibration (approximately 5 minutes after no-flow cardiac arrest), coronary perfusion and cerebral blood flows stop. The goal of cardiopulmonary resuscitation (CPR) thus is to maintain oxygen and blood supply to vital organs, restore spontaneous circulation, minimize postresuscitation organ injury, and ultimately improve the patient's survival and neurologic outcome.

The history of CPR traces back to the biblical age. However, the more contemporary approach to CPR dates back to the 1950s.[9] James Elam and Peter Safar showed that the earlier methods of resuscitation with chest-pressure and arm-lift were ineffective, and that mouth-to-mouth ventilation was an easily learned and life-saving approach. William B. Kouwenhoven of Johns Hopkins University is credited with introducing a formalized system of chest compressions. Claude Beck of Case Western Reserve University and Paul Zoll of Beth Israel Hospital introduced defibrillation to break ventricular fibrillation. In 1966 the National Academy of Sciences National Research Council conference generated consensus standards for the performance of CPR and opened the modern era of CPR.

The mechanism through which chest compressions generate blood flow can be explained by the thoracic or cardiac pump theories. The thoracic pump theory postulates that blood flows from the thorax when the intrathoracic vascular pressures exceed extrathoracic pressures.[10] The venous-to-arterial blood flow direction is a result of venous valves that prevent retrograde flow at the thoracic inlet. According to the cardiac pump theory, blood flow is generated as a result of actual compression of the heart between the sternum and the vertebral column.[11,12] Transesophageal echocardiography (TEE) during CPR in humans allowed direct visualization of changes in cardiac chambers and valve functions during chest compressions, as well as the direction of blood flow. During chest compression, the tricuspid and mitral valves close, the left and right ventricular volumes decrease, and blood is ejected into the arterial system.[13,14] During the decompression phase of CPR, the pressure gradient between the systemic venous system and thoracic cavity facilitates blood flow into the heart chambers. Systemic blood flow during CPR is dependent on effective chest compressions but also on the venous blood return to the heart. Therefore, even modest increases in the intrathoracic pressure, as might occur with overzealous ventilation during CPR, will impair venous return and negatively impact systemic, coronary, and cerebral perfusions and also reduce the chances of return of spontaneous circulation (ROSC).

Cardiac output during CPR with effective, uninterrupted chest compression is at best 25% to 30% of the normal spontaneous circulation. In cardiac arrests without hypoxic causes (e.g., suffocation, drowning), oxygen content in the lungs at the time of cardiac arrest is usually sufficient for maintaining acceptable arterial oxygen content during the first several minutes of CPR. Blood flow rather than arterial oxygen content is the limiting factor for oxygen delivery to coronary, cerebral, and systemic circulation during CPR. Thus rescue breaths are less important than initiating effective chest compressions as soon as possible after SCA.

Understanding the pathophysiology during SCA and CPR is vitally important. The actual improvement of patient outcome, however, relies on development and implementation of vigorous and evidence-based resuscitation guidelines. The more recent recommendations, the 2015 American Heart Association Guidelines for Cardiopulmonary Resuscitation



Verify scene safety.
Victim is unresponsive.
Shout for nearby help.
Activate emergency response system via mobile device (if appropriate).
Get AED and emergency equipment (or send someone to do so).
Normal breathing, has pulse
Monitor until emergency responders arrive.
Look for no breathing or only gasping and check pulse (simultaneously).
Is pulse definitely felt within 10 seconds?
No normal breathing, has pulse
Provide rescue breathing:
1 breath every 5-6 seconds, or about 10-12 breaths/min.
• Activate emergency response system (if not already done) after 2 minutes.
• Continue rescue breathing; check pulse about every 2 minutes. If no pulse, begin CPR (go to "CPR" box).
• If possible opioid overdose, administer naloxone if available per protocol.
No breathing or only gasping, no pulse
By this time in all scenarios, emergency response system or backup is activated, and AED and emergency equipment are retrieved or someone is retrieving them.
CPR
Begin cycles of 30 compressions and 2 breaths.
Use AED as soon as it is available.
AED arrives.
Check rhythm.
Shockable rhythm?
Yes, shockable
No, nonshockable
Give 1 shock. Resume CPR immediately for about 2 minutes (until prompted by AED to allow rhythm check).
Continue until ALS providers take over or victim starts to move.
Resume CPR immediately for about 2 minutes (until prompted by AED to allow rhythm check).
Continue until ALS providers take over or victim starts to move.

(From Kleinman ME, Brennan EE, Goldberger ZD, et al. Part 5: Adult Basic Life Support and Cardiopulmonary Resuscitation Quality: 2015 American Heart Association Guidelines Update for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation*. 2015;132[18 suppl 2]: S414–S435.)

and Emergency Cardiovascular Care (2015 American Heart Association [AHA] Guidelines for CPR and ECC), represent the fourth internationally recognized resuscitation guidelines from the AHA and the European Resuscitation Council; therefore, these guidelines are practiced in many countries and medical specialties. More recently, the guidelines underwent a major updating process change. Instead of updating guidelines every 5 years, the new process involves a continuous evidence evaluation process and annual guidelines update, with the most recent one being the 2017 AHA Guidelines for CPR and ECC update. The intent of this chapter is to review the history, rationale, and current understanding of both basic life support (BLS) and advanced cardiovascular life support (ACLS) techniques based on the most recent updated guidelines.

BASIC LIFE SUPPORT

BLS is, according to the Carnegie Safety Institute, the foundation for saving lives after cardiac arrest. Fundamental aspects of adult BLS include immediate recognition of SCA and activation of the emergency response system, early CPR, and rapid defibrillation with an automated external defibrillator (AED). Initial recognition and response to heart attack and stroke are also considered as parts of the BLS. All BLS interventions are time sensitive for preventing SCA, terminating SCA, or supporting circulation until spontaneous circulation is restored. The steps of the adult BLS algorithm for healthcare providers are illustrated in Fig. 86.1.

TABLE 86.1 Summary of Components of High-Quality Cardiopulmonary Resuscitation

Component	Adults and Adolescents	Children (Age 1 Year to Puberty)	Infants (Age Less Than 1 Year, Excluding Newborns)
Scene safety	Make sure the environment is safe for rescuers and victim		
Recognition of cardiac arrest	Check for responsiveness No breathing or only gasping (i.e., no normal breathing) No definite pulse felt within 10 s (Breathing and pulse check can be performed simultaneously in less than 10 s)		
Activation of emergency response system	If you are alone with no mobile phone, leave the victim to activate the emergency response system and get the AED before beginning CPR Otherwise, send someone and begin CPR immediately; use the AED as soon as it is available	*Witnessed collapse* Follow steps for adults and adolescents on the left *Unwitnessed collapse* Give 2 min of CPR Leave the victim to activate the emergency response system and get the AED Return to the child or infant and resume CPR; use the AED as soon as it is available	
Compression-ventilation ratio *without advanced airway*	*1 or 2 rescuers* 30:2	*1 rescuer* 30:2 *2 or more rescuers* 15:2	
Compression-ventilation ratio *with advanced airway*	Continuous compressions at a rate of 100-120/min Give 1 breath every 6 s (10 breaths/min)		
Compression rate	100-120/min		
Compression depth	At least 2 inches (5 cm)*	At least one-third AP diameter of chest About 2 inches (5 cm)	At least one-third AP diameter of chest About 1 1/2 inches (4 cm)
Hand placement	2 hands on the lower half of the breastbone (sternum)	2 hands or 1 hand (optional for very small child) on the lower half of the breastbone (sternum)	*1 rescuer* 2 fingers in the center of the chest, just below the nipple line *2 or more rescuers* 2 thumb–encircling hands in the center of the chest, just below the nipple line
Chest recoil	Allow full recoil of chest after each compression; do not lean on the chest after each compression		
Minimizing interruptions	Limit interruptions in chest compressions to less than 10 s		

*Compression depth should be no more than 2.4 inches (6 cm).

AED, Automated external defibrillator; *AP*, anteroposterior; *CPR*, cardiopulmonary resuscitation.

From Kleinman ME, Brennan EE, Goldberger ZD, et al. Part 5: Adult Basic Life Support and Cardiopulmonary Resuscitation Quality: 2015 American Heart Association Guidelines Update for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation*. 2015;132[18 suppl 2]:S414–S435. https://ecc-guidelines.heart.org/index.php/circulation/cpr-ecc-guidelines-2/part-5-adult-basic-life-support-and-cardiopulmonary-resuscitation-quality/.

The 2015 AHA Guidelines for CPR and ECC on BLS continue to emphasize the simplified universal adult BLS algorithm. The recommended sequence for a single rescuer is to initiate chest compressions before giving rescue breaths (circulation, airway, breathing [C-A-B] rather than airway, breathing, circulation [A-B-C]) to reduce any delay in providing effective chest compressions in adults without any known information of possible asphyxiation as the cause of cardiac arrest. The single rescuer should begin CPR with 30 chest compressions followed by 2 breaths. The guideline, in addition, also emphasizes a simultaneous, choreographed approach to the performance of chest compressions, airway management, rescue breathing, rhythm detection, and shocks (if indicated) by an integrated team of highly trained rescuers in applicable settings such as the hospital environment. With the current rhythm analysis technology, pause of chest compressions may still be required for accurate rhythm analysis, but the compressions should be resumed as soon as possible after rhythm analysis or defibrillation. The key components of high-quality CPR for BLS providers are summarized in Table 86.1.

Recognition of Sudden Cardiac Arrest

The necessary first step in the management of cardiac arrest is its immediate recognition. Studies have shown that both lay rescuers and healthcare providers have difficulty detecting a weak pulse.[15] The healthcare provider should take no more than 10 seconds to check for a pulse and, if the rescuer does not definitely feel a pulse within that time period, start chest compressions. Ideally, the pulse check is performed simultaneously with the examination for breathing or gasping, to minimize delay in the detection of cardiac arrest and initiation of CPR. Cardiac arrest victims sometimes present with seizure-like activity or agonal gasps that can confuse potential rescuers. If the victim is unresponsive with absent or abnormal breathing, the rescuer should assume that the victim is in cardiac arrest.

Bystander Cardiopulmonary Resuscitation

For victims of OHCA, the key determinants of survival are timely performance of high-quality bystander CPR and, in the presence of any of the shockable rhythms of ventricular fibrillation or pulseless ventricular tachycardia (VT), defibrillation. Similarly, for IHCA, the important provider-dependent determinants of survival are early defibrillation for shockable rhythms and high-quality CPR, along with recognition and response to deteriorating patients before an arrest. The implication of timely CPR is discussed in the next section of this chapter. The components of high-quality CPR include compressing the chest at an adequate rate and depth, allowing complete chest recoil after each compression, minimizing interruptions in compressions, and avoiding excessive ventilation.

As previously described, chest compressions create blood flow by increasing the intrathoracic pressure and directly compressing the heart. The 2015 AHA Guidelines for CPR and ECC recommended a chest compression rate of 100 to 120/min (updated from at least 100/min), and a chest compression depth for adults of at least 2 inches (5 cm) but not greater than 2.4 inches (6 cm). Despite the "push hard and push fast" recommendation, most CPR feedback devices have shown that compressions are more often too shallow than too deep.[16] In clinical practice, the compression depth may be difficult to judge without the use of feedback devices, and identification of upper limits of compression depth may be challenging. The addition of an upper limit of compression rate is based on a large registry study analysis associating extremely rapid compression rates (greater than 140/min) with inadequate compression depth.[17] Overzealous and rapid chest compressions also compromise chest recoil and venous return, and can potentially have adverse effects on patient survival and outcome.

The total number of compressions delivered during resuscitation is an important determinant of ROSC and survival with good neurologic function from cardiac arrest.[18,19] The number of compressions delivered is affected by the compression rate (the frequency of chest compressions per minute) and by the compression fraction (the portion of total CPR time during which compressions are performed). Obviously, increases in compression rate and fraction increase the total number of compressions delivered. Compression fraction is improved by reducing the number and duration of any interruptions in compressions (such as securing the airway, delivering rescue breaths, or allowing AED analysis).

Compression-only CPR is easy for an untrained rescuer to perform and can be more effectively guided by dispatchers over the telephone. Moreover, survival rates from adult cardiac arrests of cardiac etiology are similar with either compression only CPR or CPR with both compressions and rescue breaths when provided before EMS arrival.[20,21] However, for the trained lay rescuer who is able, the recommendation remains for the rescuer to perform both compressions and breaths, especially for victims with asphyxiation causes of cardiac arrest or prolonged CPR. The same emphasis on rescue breathing should also apply to the pediatric population. All lay rescuers should, at a minimum, provide chest compressions for victims of cardiac arrest. The rescuer should continue CPR until an AED arrives and is ready for use, EMS providers take over care of the victim, or the victim starts to move.

The 2015 AHA Guidelines for CPR and ECC emphasize the initiation of chest compressions before ventilation (i.e., a change in the sequence from A-B-C to C-A-B). The prioritization of circulation (C) over ventilation reflected the overriding importance of blood flow generation for successful resuscitation and practical delays inherent to initiation of rescue breaths (B). Physiologically, in most cases of SCA, the need for assisted ventilation is a lower priority because of the availability of adequate arterial oxygen content at the time of a SCA. The presence of this oxygen and its renewal through gasping and chest compressions (provided there is a patent airway) also supported the use of compression-only CPR and the use of passive oxygen delivery.

Shock First or Chest Compressions?

Previous guidelines recommended a period of chest compressions before attempting defibrillation in unwitnessed cardiac arrests or when CPR had been delayed longer than 4 minutes. However, two recent randomized control trials failed to demonstrate a benefit (ROSC or hospital discharge) when CPR was performed before defibrillation.[22,23] Thus the 2015 AHA Guidelines for CPR and ECC recommend that for adult witnessed cardiac arrests when an AED is immediately available, the defibrillator should be used as soon as possible. For adults with unmonitored cardiac arrest or for whom an AED is not immediately available, it is reasonable that chest compressions be initiated while the defibrillator equipment is being retrieved and applied, and that defibrillation, if indicated, be attempted as soon as the device is ready for use.

Automated External Defibrillators and Manual Defibrillation

Ventricular fibrillation (VF) and pulseless VT are the most common cardiac arrhythmias encountered during witnessed cardiac arrest in adults. CPR prolongs tissue viability and the duration of VF by providing oxygen and energy substrate, but cannot convert the arrhythmia to an organized rhythm in most circumstances. Defibrillation delivers an electrical current passing through the myocardium to interrupt disorganized cardiac activity and restore an organized cardiac rhythm.[24]

The first AED was introduced in 1979.[25] When it is applied to an individual with possible SCA, the AED analyzes the cardiac rhythm, and then automatically attempts defibrillation if it is VF or rapid VT. A trained rescuer needs to simply apply the defibrillator pads to the patient's chest, activate the AED, and deliver the shock through the push of a button when prompted to do so by the AED. Thus the purpose is to have early defibrillation more readily available through trained bystanders, such as security guards, police, and the general public.

When a standard manual defibrillator is used in resuscitation, the rescuer needs to interpret the rhythm and shock when appropriate. If a monophasic defibrillator is available, then a single 360 joule (J) shock should be delivered. With biphasic defibrillators, a much lower energy level (150-200 J) is usually sufficient to terminate the arrhythmia due to its ability to compensate and adjust for the patient's impedance. If the rescuer is unfamiliar with the waveform used or the manufacturer recommendations, then the maximal available energy should be used as the default energy. There is no evidence indicating superiority of one biphasic waveform design or energy level for the termination of VF with the first shock. For subsequent shocks, it is reasonable to select fixed versus escalating energy based on the specific manufacturer's instructions.

The same protocol used with the AED should be applied when using the manual defibrillator: (1) emphasis is placed on delivering uninterrupted chest compressions while defibrillator pads are being applied and for periods when rhythm analysis is not occurring; (2) chest compressions are immediately resumed after shock delivery; (3) cardiac rhythm is reanalyzed as indicated after 2 minutes of chest compressions and rescue breathing; and (4) defibrillation is attempted only for VF and rapid VT.[26]

Single versus Stacked Defibrillation

The 2015 AHA Guidelines for CPR and ECC recommended a 2-minute period of chest compressions after each shock instead of immediate successive shocks for persistent VF.[27] The rationale for this is that when VF is terminated, a brief period of asystole or pulseless electrical activity (PEA) typically ensues and a perfusing rhythm is unlikely to be present immediately, necessitating chest compressions to provide organ perfusion and circulation of ACLS drugs. No difference in the 1-year survival or frequency of VF recurrence was shown when a single shock protocol with 2 minutes of CPR between successive shocks was compared against a previous resuscitation protocol employing three initial stacked shocks with 1 minute of CPR between subsequent shocks.[28,29] A recent study demonstrated that in monitored in-hospital VF/VT arrests, expeditious defibrillation with use of stacked shocks is associated with a higher rate of ROSC and survival to hospital discharge.[30] Without further data, current AHA guidelines recommend that a single-shock strategy (as opposed to stacked shocks) is reasonable for defibrillation. Stacked defibrillation is considered only during cardiac surgery or in the cardiac catheterization laboratory where invasive monitoring and defibrillation pads are in place already.

Determination of Efficiency of Cardiopulmonary Resuscitation

Immediately after cardiac arrest, when minute ventilation is constant and carbon dioxide (CO_2) production is unchanged, the changes in the partial pressure of end-tidal CO_2 ($PETCO_2$) can serve as a reliable surrogate for pulmonary blood flow and cardiac output. This has been proven extensively by animal and human studies during cardiac arrest and CPR and after ROSC.[31-33] Monitoring of both $PETCO_2$ by quantitative waveform capnography with controlled ventilation and systemic arterial pressure by invasive monitoring should provide optimal assessment of the efficiency of CPR. These parameters can be monitored continuously, without interrupting chest compressions. An abrupt increase in any of these parameters is a sensitive indicator of ROSC. The 2015 AHA Guidelines for CPR and ECC endorse this monitoring as a class I recommendation for adults with SCA with an endotracheal tube (ETT) or supraglottic airway (SGA) device in place. In addition, coronary perfusion pressure, arterial relaxation pressure, and central venous oxygen saturation can assist in determination of the efficiency of CPR, although these monitoring techniques require more complex catheters or devices.[34,35] Currently there are no clinical trials that have studied whether titrating resuscitative efforts to a single or combined set of physiologic parameters during CPR results in improved survival or neurologic outcome. However, the 2010 AHA Guidelines for CPR and ECC recommended that $PETCO_2$ should be maintained above 10 mm Hg,[36] and mathematical models suggest a cumulative maximum $PETCO_2$ above 20 mm Hg at all time points measured between 5 and 10 minutes postintubation best predicted ROSC.[37]

Update to Airway Management and Ventilation in Cardiac Arrest

When cardiac arrest occurs, adequate oxygen delivery is required to restore the energy state of the heart as well as other vital organs, and consequently ventilation becomes an essential part of the resuscitation. However, it also needs to be emphasized that during the first few minutes after cardiac arrest, oxygen delivery to tissues with CPR is limited more by blood flow and low cardiac output than arterial oxygen content.[38] Low cardiac output associated with CPR results in low oxygen uptake from the lungs that, in turn, reduces the need to ventilate the patient during this low-flow state.[38] Thus chest compressions are the priority intervention, unless the cardiac arrest is due to asphyxiation, drowning, or suffocation, which are the only circumstances in which ventilation must be provided before chest compressions.[39]

Healthcare providers must determine the best way to support ventilation and oxygenation. Options include standard bag-mask ventilation versus placement of an advanced airway (i.e., ETT or SGA device). Bag-mask ventilation with a head tilt–chin lift or head tilt–jaw thrust maneuver is recommended for initial airway control in most circumstances. There is inadequate evidence to show a difference in survival or favorable neurologic outcome with the use of bag-mask ventilation compared with endotracheal intubation or other advanced airway devices.[40,41] There is also inadequate evidence favoring the use of endotracheal intubation compared with other advanced airway devices.[42] Thus 2015 AHA/Guidelines for CPR and ECC recommend that either a bag-mask device or an advanced airway may be used for oxygenation and ventilation during CPR in both the in-hospital and out-of-hospital settings, assuming that providers have ongoing experience to insert the airway and verify proper position with minimal interruption in chest compressions. The choice of bag-mask device versus advanced airway insertion is determined by the skill and experience of the provider.

Regarding the inspired oxygen concentration, the 2015 AHA Guidelines for CPR and ECC support providing the maximal inspired oxygen concentration during CPR. Since oxygen delivery is dependent on both blood flow and arterial oxygen content and blood flow is typically limited during CPR, it is theoretically important to maximize the oxygen content of arterial blood by maximizing inspired oxygen concentration. Evidence for the detrimental effects of hyperoxia that may exist in the immediate post–cardiac arrest period should not be extrapolated to the low-flow state of CPR, where oxygen delivery is unlikely to exceed demand or cause an increase in tissue PO_2. Therefore, until further data are available, physiology and expert consensus support providing the maximal inspired oxygen concentration during CPR.

After ETT placement, it is very important to confirm its correct placement, although this could be very challenging due to the patient's body habitus, low-flow status, and distraction from other resuscitative tasks. In addition to observation of chest rise and auscultation of the lungs and stomach, continuous waveform capnography is recommended as the most reliable method of confirming and monitoring correct placement of an ETT.[43] However, false-positive results (CO_2 detection with esophageal intubation) can still occur, especially within the first few breaths due to air/CO_2 insufflation of the stomach during bag-mask ventilation. False-negative results (i.e., absent exhaled CO_2 in the presence of tracheal intubation) can occur in the setting of pulmonary embolism (PE), low cardiac output, or severe obstructive pulmonary disease. If continuous waveform capnography is not available, a nonwaveform CO_2 detector, fiberoptic scope, esophageal detector, or ultrasound device used by an experienced operator are reasonable alternatives.

If bag-mask ventilation is chosen, 2 breaths are delivered after 30 chest compressions during one- and two-person CPR, providing that the rescuer(s) is(are) trained in CPR. Each breath is delivered over approximately 1 second. After placement of an advanced airway, it is recommended to provide 1 breath every 6 seconds (10 breaths/min) while continuous chest compressions are being performed. Extreme caution should be taken to avoid excessive airway pressure that will compromise venous return in cardiac arrest patients, as hyperventilation is common during enthusiastic resuscitation.

ADVANCED CARDIAC LIFE SUPPORT: MANAGEMENT OF CARDIAC ARREST

BLS, ACLS, and post–cardiac arrest care are integral steps in the AHA's "chain of survival" for patients suffering from cardiac arrest. CPR almost invariably necessitates rapid progression to ACLS interventions and follow-up care. There is overlap between these steps, as each stage of care progresses to the next, but generally ACLS comprises the level of care between BLS and post–cardiac arrest care. The 2015 AHA Guidelines for CPR and ECC adult cardiac arrest algorithm is illustrated in Fig. 86.2. This section reviews the different interventions for managing cardiac arrest patients based on the presenting ECG rhythm, medications used during cardiac arrest, special situations of cardiac arrest, and new technologies developed to facilitate resuscitation and improve the patient's survival.

Asystole

Asystole is the complete and sustained absence of electrical activity and portends extremely poor prognosis. Management of a patient in cardiac arrest with asystole follows the same pathway as management of PEA (as discussed later). The top priorities are also similar: following the steps in the ACLS Pulseless Arrest Algorithm and identifying and correcting any treatable, underlying causes for the asystole. In most patients, asystole is irreversible, but a brief trial of resuscitation, beginning with effective chest compressions, oxygen therapy, and intravenous (IV) epinephrine, is indicated particularly in the setting of witnessed cardiac arrest. Atropine is no longer recommended for treating asystole. Asystole should be differentiated from agonal bradycardia and fine ventricular fibrillation.

Pulseless Electrical Activity

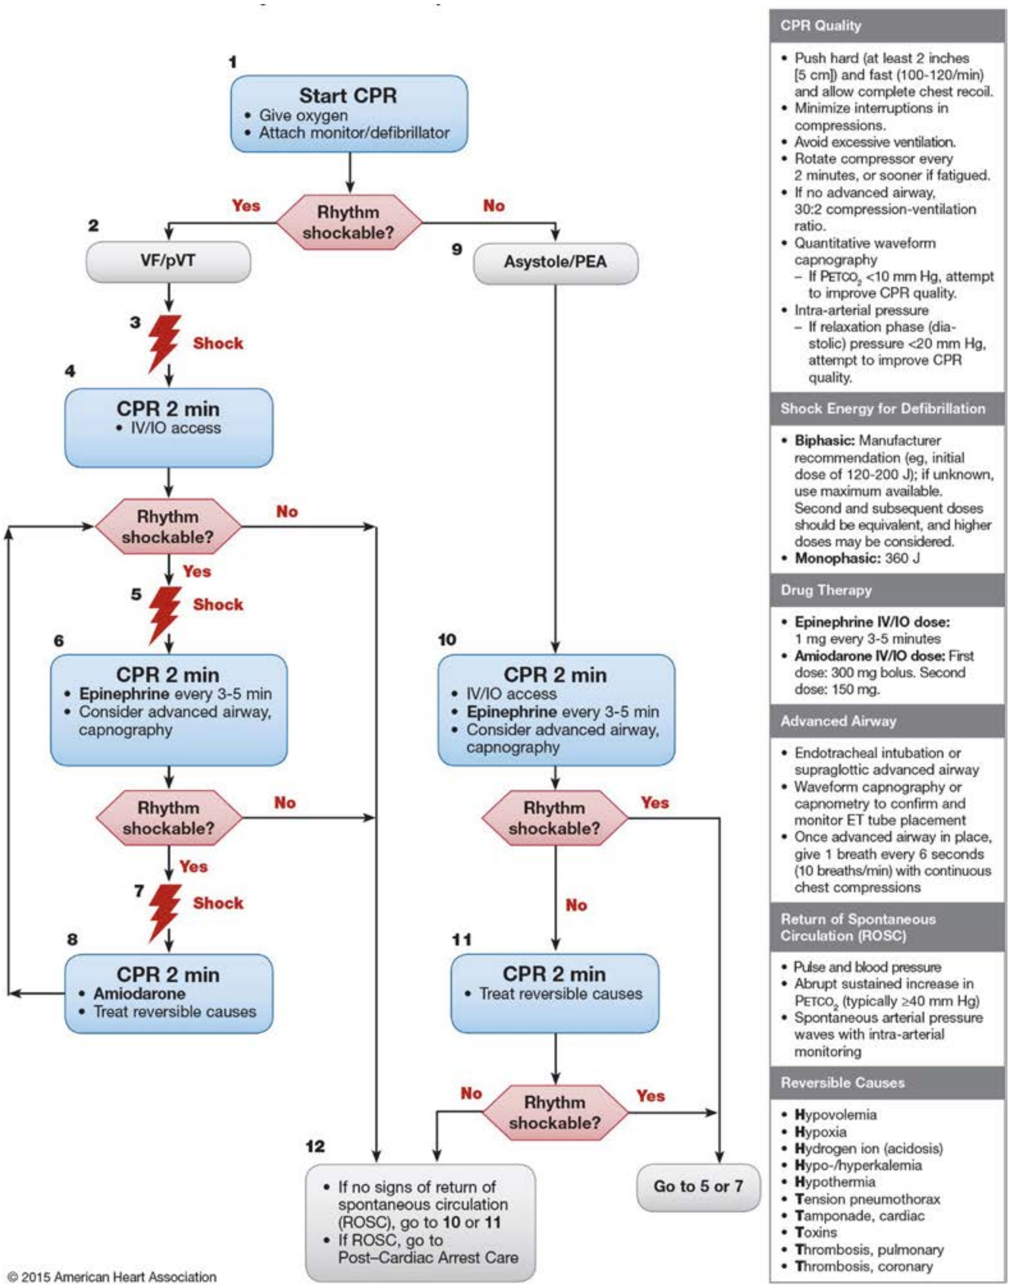
PEA refers to the presence of organized electrical activity without a palpable pulse. Priority must be given to identifying possible reversible causes of PEA, which is frequently referred to as the five Hs (Hypoxia, Hypovolemia, Hypothermia, Hyper- or Hypokalemia, Hydrogen ions or acidosis) and Ts (Tamponade, Tension pneumothorax, Toxins, Thrombosis Pulmonary, and Thrombosis Coronary). Those causes are first suspected for each patient's special circumstance. Severe hypoxia in respiratory emergencies can result in PEA. In the traumatized patient, hypovolemia, cardiac tamponade, and tension pneumothorax are possible causes of cardiac arrest and must be considered and acutely treated. Unanticipated cardiac arrest occurring in the intraoperative and postoperative periods should include acute massive pulmonary thromboembolism or air emboli as possible causes. Electrolyte and metabolic derangements such as severe hyperkalemia, metabolic acidosis, or drug (e.g., digitalis, β-blockers, calcium channel blockers, tricyclic antidepressants) overdose frequently presents as idioventricular rhythms. In every circumstance, prompt initiation of chest compressions and the administration of 1 mg epinephrine are recommended as temporizing measures until more definitive therapy can be provided once the cause for the PEA is identified. Each of these scenarios has an associated intervention unique to that situation. Asystole or VF can develop if PEA is not corrected.

Pulseless Ventricular Tachycardia or Ventricular Fibrillation

Pulseless VT and VF are shockable rhythms and hence the most treatable causes of cardiac arrest, yielding the greatest likelihood of ROSC and long-term survival in both in-hospital and out-of-hospital settings. Early defibrillation, not pharmacologic intervention, is responsible for the improved survival after VF cardiac arrest. Therefore, AEDs are placed in public locations to ensure early defibrillation can be performed by rescuers.

When a pulseless VT or VF arrest occurs, defibrillation should be performed at the earliest opportunity. Chest compressions should be immediately resumed after the delivery of shock and continued for 2 minutes before reassessing the underlying cardiac rhythm, unless obvious evidence for ROSC occurs. No evidence supports one biphasic waveform over another. Defibrillation energies should be increased until VF is terminated. In circumstances in which pulseless VT or VF is terminated with defibrillation but pulseless VT or VF recurs, defibrillation should use the previously successful energy level.

If ROSC does not occur after an initial defibrillatory attempt, then five cycles of CPR consisting of 30



1
Start CPR
• Give oxygen
• Attach monitor/defibrillator
Rhythm shockable?
Yes
No
2

CPR Quality

- Push hard (at least 2 inches [5 cm]) and fast (100-120/min) and allow complete chest recoil.
- Minimize interruptions in compressions.
- Avoid excessive ventilation.
- Rotate compressor every 2 minutes, or sooner if fatigued.
- If no advanced airway, 30:2 compression-ventilation ratio.
- Quantitative waveform capnography
  - If P_{ETCO_2} <10 mm Hg, attempt to improve CPR quality.
- Intra-arterial pressure
  - If relaxation phase (diastolic) pressure <20 mm Hg, attempt to improve CPR quality.

Shock Energy for Defibrillation

- **Biphasic:** Manufacturer recommendation (eg, initial dose of 120-200 J); if unknown, use maximum available. Second and subsequent doses should be equivalent, and higher doses may be considered.
- **Monophasic:** 360 J

Drug Therapy

- **Epinephrine IV/IO dose:** 1 mg every 3-5 minutes
- **Amiodarone IV/IO dose:** First dose: 300 mg bolus. Second dose: 150 mg.

Advanced Airway

- Endotracheal intubation or supraglottic advanced airway
- Waveform capnography or capnometry to confirm and monitor ET tube placement
- Once advanced airway in place, give 1 breath every 6 seconds (10 breaths/min) with continuous chest compressions

Return of Spontaneous Circulation (ROSC)

- Pulse and blood pressure
- Abrupt sustained increase in P_{ETCO_2} (typically ≥40 mm Hg)
- Spontaneous arterial pressure waves with intra-arterial monitoring

Reversible Causes

- **H**ypovolemia
- **H**ypoxia
- **H**ydrogen ion (acidosis)
- **H**ypo-/hyperkalemia
- **H**ypothermia
- **T**ension pneumothorax
- **T**amponade, cardiac
- **T**oxins
- **T**hrombosis, pulmonary
- **T**hrombosis, coronary

Fig. 86.2 2015 American Heart Association adult advanced cardiovascular life support algorithm. *CPR*, Cardiopulmonary resuscitation; *IO*, intraosseous; *IV*, intravenous; *PEA*, pulseless electric activity; *VF*, ventricular fibrillation; *VT*, ventricular tachycardia. (From Link MS, Berkow LC, Kudenchuk PJ, et al. Part 7: Adult Advanced Cardiovascular Life Support: 2015 American Heart Association Guidelines Update for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation*. 2015;132[18 suppl 2]:S444–S464.)

compressions to 2 ventilations (nonintubated patient) should be performed before recheck of rhythm. Placement of a SGA device or endotracheal intubation can be considered in this interval. Peripheral IV access should be attempted if not already established without interruption of the chest compressions.

Resuscitation Medications During Cardiac Arrest

Epinephrine. Epinephrine produces beneficial effects in patients during cardiac arrest, primarily due to its α-adrenergic effects increasing coronary perfusion pressure and cerebral perfusion pressure during CPR. The β-adrenergic effects of epinephrine are controversial because they may increase myocardial work and reduce subendocardial perfusion. Thus standard-dose epinephrine (1 mg every 3-5 minutes) is recommended for patients in cardiac arrest. High-dose epinephrine is not recommended for routine use in cardiac arrest. The exceptions to this recommendation are special circumstances requiring higher or repeated doses of epinephrine, such as in patients with β-blocker overdose, calcium channel blocker overdose, or when epinephrine is titrated to real-time physiologically monitored parameters.

Regarding the timing of epinephrine administration, multiple trials showed the early administration of epinephrine in nonshockable rhythms (asystole or PEA) was associated with increased ROSC, survival to hospital discharge, and neurologically intact survival.[44,45] For shockable rhythms (VF or pulseless VT), there is insufficient evidence to make a recommendation as to the optimal timing of epinephrine, particularly in relation to defibrillation. Therefore early administration of epinephrine is recommended after the onset of cardiac arrest caused by an initial nonshockable rhythm.

Vasopressin. Vasopressin is a nonadrenergic peripheral vasoconstrictor that also causes coronary and renal vasoconstriction. Studies compared multiple doses of standard-dose epinephrine with multiple doses of vasopressin (40 units IV) or vasopressin in combination with epinephrine after OHCA and showed no benefit with the use of vasopressin solely or in combination with epinephrine for ROSC or survival to discharge with or without good neurologic outcome.[46] Vasopressin offers no advantage as a substitute for epinephrine in cardiac arrest and thus has been removed from the adult cardiac arrest algorithm.

Antiarrthymia Medications. The role of antiarrhythmic medications during shock-refractory VF/pulseless VT is to facilitate the restoration and maintenance of a spontaneous perfusing rhythm in concert with the shock termination of VF, instead of directly converting VF/pulseless VT to an organized perfusing rhythm. Some antiarrhythmic drugs have been associated with increased rates of ROSC and hospital admission, but none have yet been proven to increase long-term survival or survival with good neurologic outcome. Thus the 2015 AHA Guidelines for CPR and ECC on ACLS recommend that amiodarone may be considered for VF/pulseless VT that is unresponsive to CPR, defibrillation, and a vasopressor therapy; and lidocaine may be considered as an alternative to amiodarone. Routine use of magnesium for VF/pulseless VT is not recommended in adult patients, nor is the routine use of sodium bicarbonate for any patient in cardiac arrest.

Steroids. The use of steroids in cardiac arrest has been assessed in both IHCA and OHCA settings. In IHCA, patients administered steroids combined with a vasopressor bundle or cocktail of epinephrine and vasopressin had improved ROSC compared with patients given a saline placebo and epinephrine.[47] However, further studies are needed before recommending the routine use of this therapeutic strategy. For patients with OHCA, studies showed inconsistent benefit of use of steroids alone during CPR and thus routine use is not recommended.

Cardiopulmonary Resuscitation in Patients With Mechanical Circulatory Support

Cardiac arrest in patients on mechanical circulatory support (MCS) has become a much more common clinical scenario due to the increased use of this therapy in patients with end-stage heart failure. Because of the unique characteristics of mechanical support, these patients have physical findings that cannot be interpreted the same as for patients without MCS. This section briefly describes the common types of MCS devices that healthcare providers may encounter and presents expert, consensus-based recommendations from the recent AHA guidelines for the evaluation and resuscitation of adult patients with MCS, and suspected cardiovascular collapse or cardiac arrest.[48]

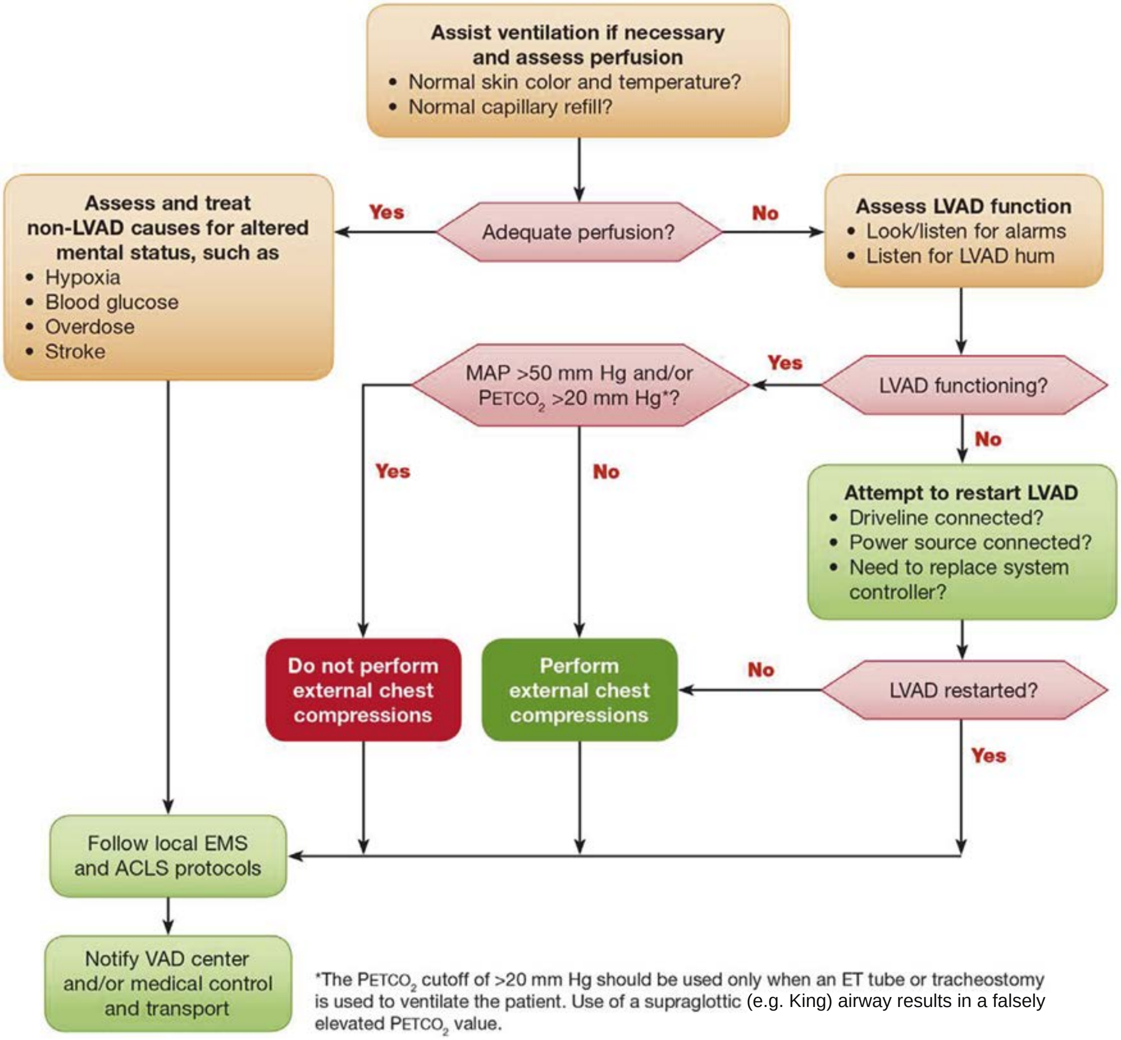
MCS with ventricular assist devices (VADs) can support function of the left ventricle (LV), the right ventricle (RV), or both ventricles with a biventricular assist device. A total artificial heart (TAH) replaces the heart itself. Most patients who are discharged home with MCS currently have a durable left ventricular VAD (LVAD). Continuous-flow LVADs are the more current generation of VADs. It results in an unconventional, unique physiologic state of hemodynamically stable PEA, which we refer to in this population as pseudo-PEA. Vital signs such as noninvasive blood pressure or oxygen saturation may be difficult to obtain. These factors can easily confuse healthcare providers rendering care to these patients. Lack of a pulse alone in a patient with a continuous-flow LVAD is common and cannot be used as a means to determine whether a patient is in cardiac arrest or a low-flow, low-perfusion state.

Assessment of adequate tissue perfusion is the most important factor in determining the need for circulatory assistance such as chest compressions. Clinical findings such as skin color and capillary refill are reasonable predictors of the presence of adequate flow and perfusion. If an LVAD is definitively confirmed by a trained person and there are no signs of life, bystander CPR, including chest compressions, is recommended. Many tachyarrhythmias are tolerated well in patients with an LVAD, although they can affect RV filling. Similar to the decision made for patients without VADs, the decision to cardiovert or to defibrillate a patient with an LVAD with VT or VF is based on the adequacy of mental status and perfusion. Fig. 86.3 outlines consensus-derived recommendations for first-responder assessment of a patient with an LVAD.

For patients with a TAH, the native ventricles are removed completely; therefore, there is no electric depolarization and therefore no detectable ECG tracing. Chest compressions are ineffective because the mechanical ventricles are rigid and cannot be compressed. Antiarrhythmic drugs and electric therapy (e.g., pacing, defibrillation/cardioversion) are also futile for similar reasons. Standard vasopressor drugs used in ACLS such as epinephrine or vasopressin are contraindicated because they increase afterload, result in complete hemodynamic collapse with pulmonary edema, and worsen TAH function. The only therapeutic option is to try to restore mechanical function of the device. One liter of normal saline solution should be administered intravenously to treat for possible hypovolemia. Assisted ventilation should be performed as needed, and the patient should be transported to the hospital as soon as possible. Fig. 86.4 provides an algorithm for evaluation and treatment of a patient with a TAH who is altered mentally, unresponsive, or in respiratory distress.

Cardiopulmonary Resuscitation Using a Mechanical Cardiopulmonary Resuscitation Device

Delivering high-quality chest compressions to achieve ROSC and maintain perfusion to vital organs is vitally important to improving survival and neurologic outcome after cardiac arrest. However, manual conventional chest compressions are frequently affected by fatigue, varying skill levels and training, pauses during defibrillation and the switch of rescuers, and adherence to protocols.[49] It is even more difficult to ensure high-quality chest compressions



Assist ventilation if necessary and assess perfusion
• Normal skin color and temperature?
• Normal capillary refill?
Adequate perfusion?
Yes
No
Assess and treat non-LVAD causes for altered mental status, such as
• Hypoxia
• Blood glucose
• Overdose
• Stroke
Assess LVAD function
• Look/listen for alarms
• Listen for LVAD hum
MAP >50 mm Hg and/or PETCO2 >20 mm Hg*?
Yes
LVAD functioning?
No
Yes
No
Attempt to restart LVAD
• Driveline connected?
• Power source connected?
• Need to replace system controller?
Do not perform external chest compressions
Perform external chest compressions
No
LVAD restarted?
Yes
Follow local EMS and ACLS protocols
Notify VAD center and/or medical control and transport

*The PETCO$_2$ cutoff of >20 mm Hg should be used only when an ET tube or tracheostomy is used to ventilate the patient. Use of a supraglottic (e.g. King) airway results in a falsely elevated PETCO$_2$ value.

Fig. 86.3 Algorithm showing response to a patient with a left ventricular assist device *(LVAD)* with unresponsiveness or other altered mental status. *ACLS*, Advanced cardiovascular life support; *EMS*, emergency medical services; *ET*, endotracheal tube; *MAP*, mean arterial pressure; *PETCO$_2$*, partial pressure of end-tidal carbon dioxide; *VAD*, ventricular assist device. (From Peberdy MA, Gluck JA, Ornato JP, et al. Cardiopulmonary Resuscitation in Adults and Children With Mechanical Circulatory Support: A Scientific Statement From the American Heart Association. *Circulation*. 2017;135[24]:e1115–e1134.)

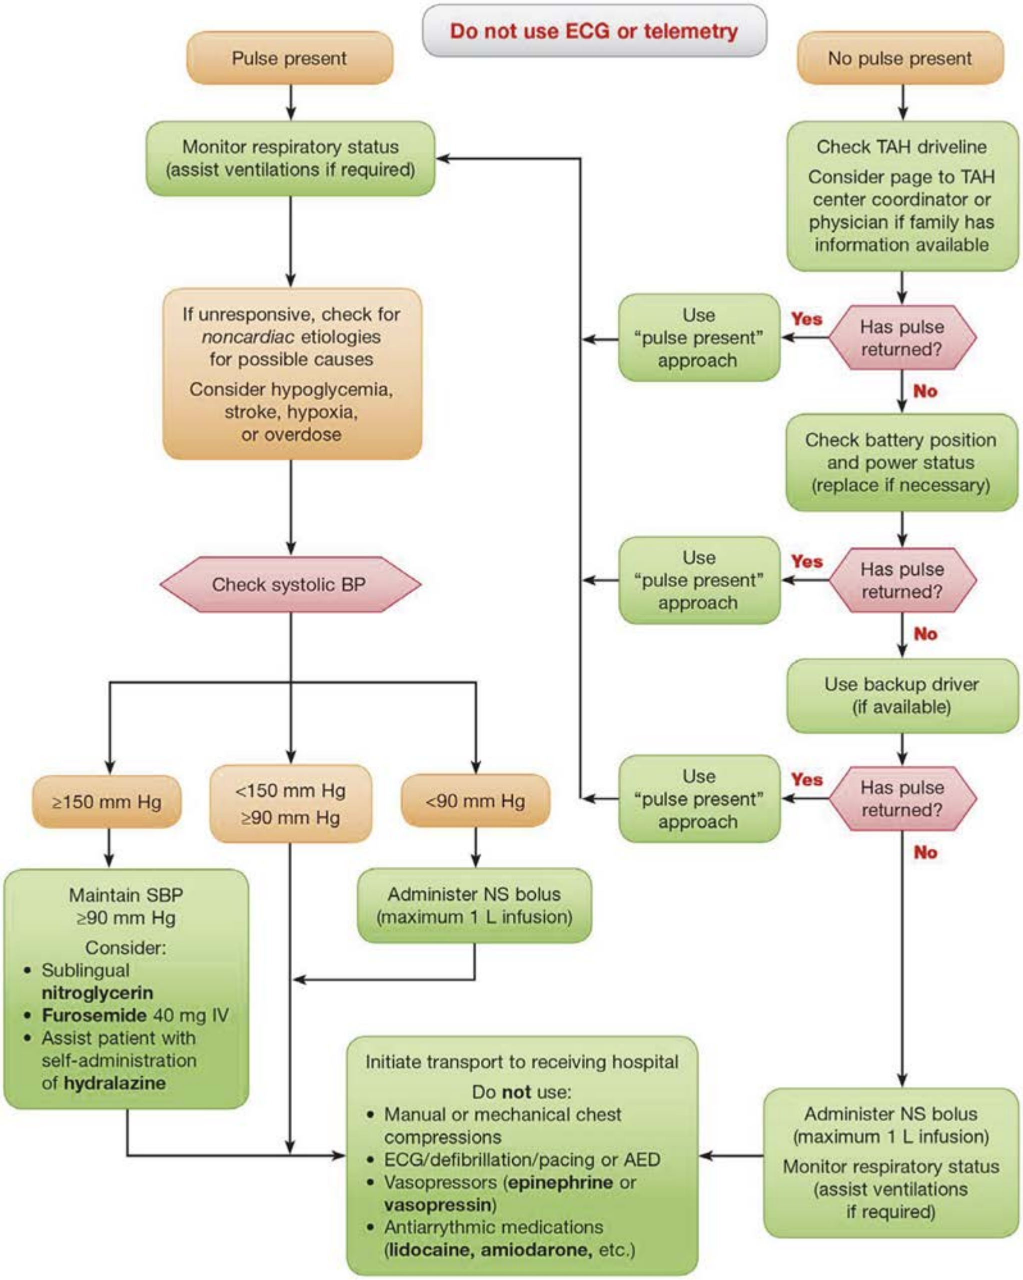
during transport.[50] Studies showed that manual compressions provide only approximately 30% of normal cardiac output, at best.[51] Mechanical chest compression devices have therefore been developed to improve CPR. These devices are designed to deliver compressions of consistent rate and depth, eliminate fatigue as a factor, and provide an opportunity to reduce the frequency and length of pauses in compression.

Initial experimental studies with the mechanical chest compression device showed improved organ perfusion pressures, enhanced cerebral blood flow, and higher end-tidal CO$_2$ compared with manual CPR.[52,53] A recent large multicenter randomized controlled trial showed, nevertheless, that an algorithm combining mechanical chest compressions and defibrillation during ongoing compressions provided no survival advantage over manual CPR administered according to guidelines.[54] No difference in survival or neurologic outcome was seen for up to 6 months after the cardiac arrest, even though the mechanical chest compression devices reduced interruptions in chest compressions, and enabled defibrillation during ongoing compressions.

The possible explanation for this discrepancy between early studies and the large clinical trial is that application of the mechanical device resulted in long pauses of chest compression (median device application time 36.0 seconds), and pause in chest compression is clearly associated with worse clinical outcome. Therefore the 2015 AHA Guidelines for CPR and ECC recommended that manual chest compressions remain the standard of care for the treatment of cardiac arrest, but mechanical CPR devices may be a reasonable alternative for use by properly trained personnel in specific settings where the delivery of high-quality manual compressions may be challenging or dangerous for the provider (e.g., limited rescuers available, prolonged CPR, during hypothermic cardiac arrest, during preparation for extracorporeal CPR [ECPR]). Future emphasis should be placed on streamlining and appropriately timing the deployment of these compression devices.

Echocardiography in Cardiac Arrest

For nonshockable rhythms, the essential step will be early detection and correction of potentially reversible underlying



Do not use ECG or telemetry
Pulse present
No pulse present
Monitor respiratory status (assist ventilations if required)
Check TAH driveline
Consider page to TAH center coordinator or physician if family has information available
If unresponsive, check for noncardiac etiologies for possible causes
Consider hypoglycemia, stroke, hypoxia, or overdose
Use "pulse present" approach
Yes
Has pulse returned?
No
Check battery position and power status (replace if necessary)
Check systolic BP
Use "pulse present" approach
Yes
Has pulse returned?
No
Use backup driver (if available)
≥150 mm Hg
<150 mm Hg ≥90 mm Hg
<90 mm Hg
Use "pulse present" approach
Yes
Has pulse returned?
No
Maintain SBP ≥90 mm Hg
Consider:
• Sublingual nitroglycerin
• Furosemide 40 mg IV
• Assist patient with self-administration of hydralazine
Administer NS bolus (maximum 1 L infusion)
Initiate transport to receiving hospital
Do not use:
• Manual or mechanical chest compressions
• ECG/defibrillation/pacing or AED
• Vasopressors (epinephrine or vasopressin)
• Antiarrythmic medications (lidocaine, amiodarone, etc.)
Administer NS bolus (maximum 1 L infusion)
Monitor respiratory status (assist ventilations if required)

Fig. 86.4 Algorithm showing response to a patient with a total artificial heart *(TAH)* with altered mental status, unresponsiveness, or respiratory distress. *AED*, Automated external defibrillator; *BP*, blood pressure; *IV*, intravenous; *NS*, normal saline; *SBP*, systolic blood pressure. causes, such as the Hs and Ts of PEA arrest, as described earlier. Echocardiography has revolutionized our ability to assess the etiology and hence the management of these patients. However, performing and interpreting echocardiography frequently proves much more challenging in the real scene of cardiac arrest.

Point-of-care (POC) focused echocardiography can help assess the volume status, ventricular function, valvular disease, cardiac tamponade, PE, and tension pneumothorax. The TEE, compared with transthoracic echocardiography, provides constant visualization of the heart during chest compressions and gives live feedback on cardiac contractility and the quality of compressions. It is less affected by the body habitus, presence of subcutaneous air, and by chest movements. Several studies have evaluated the feasibility and clinical influence of TEE in cardiac arrest patients. TEE showed moderate sensitivity and specificity for diagnosing cause of arrest, and may further impact treatment.[55,56] However, it is unclear if these benefits will be translated to improved patient outcome. Thus the 2015 AHA Guidelines for CPR and ECC suggested that if a qualified sonographer is present and use of ultrasound does not interfere with the standard cardiac arrest treatment protocol, then ultrasound may be considered as an adjunct to standard patient evaluation and resuscitation measures.

More recently, POC focused echocardiography has also been used to predict short-term outcome in patients with cardiac arrest. Recent meta-analysis showed spontaneous cardiac movement had a sensitivity of 95% and specificity of 80% to predict ROSC, and sensitivity 90% and specificity 78% to predict survival to hospital admission.[57] Absence of spontaneous cardiac movement on echocardiography has a low likelihood of favorable outcome and can aid in the decision of termination of resuscitation. The caveat is that the interpretation of spontaneous cardiac movement is still very operator-dependent. In addition, in cases of significant bradycardia, the image could be potentially interpreted as cardiac standstill between the cardiac contractions.

Cardiac or Respiratory Arrest Associated With Opioid Overdose

In the United States in 2013, 16,235 people died of prescription opioid toxicity, and an additional 8257 died of heroin overdose.[58] In 2012, opioid overdose became the leading cause of unintentional injurious death in people aged 25 to 60 years in the United States, accounting for more deaths than motor vehicle collisions.[59] A majority of these deaths are associated with prescription opioids. In consideration of this epidemiology, the 2015 AHA Guidelines for CPR and ECC on BLS recommended that for patients with known or suspected opioid addiction who are unresponsive with no normal breathing but a pulse, it is reasonable for appropriately trained lay rescuers and BLS providers, in addition to providing standard BLS care, to administer intramuscular (IM) or intranasal naloxone.

The ideal dose of naloxone is unknown. In the 2010 AHA Guidelines for CPR and ECC, an empiric starting dose of 0.04 to 0.4 mg IV or IM was recommended to avoid provoking severe opioid withdrawal in patients with opioid dependency and to allow for consideration of a range of doses, depending on the clinical scenario. Repeat doses or dose escalation to 2 mg IV or IM was recommended if the initial response was inadequate. Regardless of the care setting and route of administration, the initial goal of therapy is to restore and maintain patent airway and ventilation, preventing respiratory and cardiac arrest, without provoking severe opioid withdrawal.

Recognition and Emergency Response for Suspected Stroke

Each year, about 6.5 million people die from stroke worldwide, and 1 million from cerebrovascular diseases in the 15 countries of the European Union.[60,61] According to the 2013 Global Burden of Disease study, stroke is the second largest contributor to disability-adjusted life years (113 million disability-adjusted life years) in the world after ischemic heart disease, is a major cause of disability, and is the second most common cause of dementia, after Alzheimer disease. Identifying clinical signs of possible stroke (sudden weakness or numbness of the face, arm, or leg, especially on one side of the body; sudden confusion, trouble speaking, or understanding; sudden trouble seeing in one or both eyes; sudden trouble walking, dizziness, loss of balance, or coordination; or sudden severe headache with no known cause) is important because fibrinolytic treatment must be provided within a few hours of onset of symptoms.[62,63] Community and professional education is essential to increase the early recognition and treatment to improve patient outcome.

The AHA and American Society of Anesthesiologists developed a community-oriented "stroke chain of survival" that links actions to be taken by patients, family members, and healthcare providers to maximize stroke recovery. Important components of this chain are rapid recognition and reaction to stroke warning signs, rapid EMS dispatch, transport and hospital pre-notification, and rapid diagnosis and treatment in the hospital. The algorithm goals for management of patients with suspected stroke is illustrated in Fig. 86.5.

Recognition and Management of Specific Arrythmias

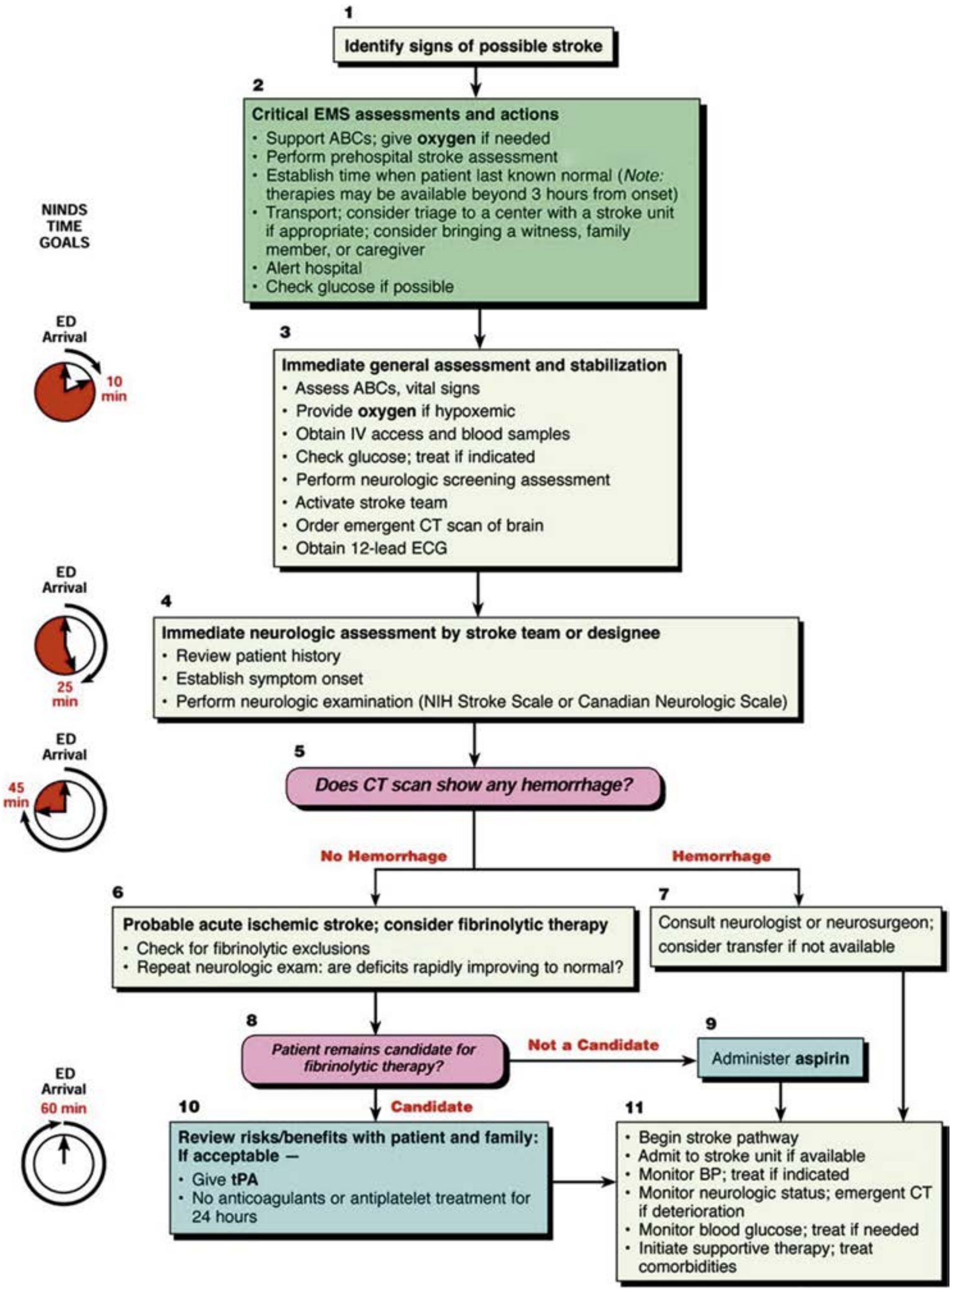
This section highlights recommendations for management of patients with acute symptomatic arrhythmias. It needs to be emphasized that electrocardiographic and rhythm information should be interpreted within the context of total patient assessment. For example, when a patient with respiratory failure and severe hypoxemia becomes hypotensive and develops a bradycardia, the bradycardia is not the primary cause of instability. Treating the bradycardia without treating the hypoxemia is unlikely to improve the patient's condition. Errors in diagnosis and treatment are likely to occur if ACLS providers base their treatment decisions solely on rhythm interpretation and neglect the clinical evaluation of each specific patient.

In general, "unstable arrhythmias" refer to a condition in which vital organ function is acutely impaired due to inefficient cardiac contractions and insufficient cardiac output, or cardiac arrest is ongoing or imminent. When an arrhythmia causes a patient to be unstable, immediate intervention is indicated. "Symptomatic arrhythmias" imply that an arrhythmia is causing symptoms, such as palpitations, lightheadedness, or dyspnea, but the patient is stable and not in imminent danger. In such cases, more time is available to decide on the most appropriate intervention. In both unstable and symptomatic cases, the provider must make an assessment as to whether the arrhythmia is causing the patient to be unstable or symptomatic. It is critically important to determine the cause of the patient's instability in order to properly direct the treatment.

BRADYARRHYTHMIAS

Bradycardia is defined as a heart rate of less than 60 beats/min. However, when bradycardia is the cause of symptoms, the rate is generally less than 50 beats/min. A slow heart rate may be physiologically normal for some patients, whereas a heart rate of more than 50 beats/min may be inadequate for others. Hence, 50 beats/min is a relative number, and it is important to also assess the patient's clinical presentation.

Depending on the origin of the arrhythmia, bradyarrhythmias can be classified as supraventricular (sinus, junctional, or various degrees of atrioventricular [AV] block) or ventricular (complete heart block with a very slow idioventricular escape rhythm). Sinus (or junctional) bradycardia and type I (AV nodal) second-degree block are usually manifestations of increased vagal tone. AV blocks are classified as first, second, and third degree. A first-degree AV block is defined



1
Identify signs of possible stroke
2
Critical EMS assessments and actions
• Support ABCs; give oxygen if needed
• Perform prehospital stroke assessment
• Establish time when patient last known normal (Note: therapies may be available beyond 3 hours from onset)
• Transport; consider triage to a center with a stroke unit if appropriate; consider bringing a witness, family member, or caregiver
• Alert hospital
• Check glucose if possible
NINDS TIME GOALS
ED Arrival
10 min
3
Immediate general assessment and stabilization
• Assess ABCs, vital signs
• Provide oxygen if hypoxemic
• Obtain IV access and blood samples
• Check glucose; treat if indicated
• Perform neurologic screening assessment
• Activate stroke team
• Order emergent CT scan of brain
• Obtain 12-lead ECG
ED Arrival
25 min
4
Immediate neurologic assessment by stroke team or designee
• Review patient history
• Establish symptom onset
• Perform neurologic examination (NIH Stroke Scale or Canadian Neurologic Scale)
ED Arrival
45 min
5
Does CT scan show any hemorrhage?
No Hemorrhage
Hemorrhage
6
Probable acute ischemic stroke; consider fibrinolytic therapy
• Check for fibrinolytic exclusions
• Repeat neurologic exam: are deficits rapidly improving to normal?
7
Consult neurologist or neurosurgeon; consider transfer if not available
8
Patient remains candidate for fibrinolytic therapy?
Not a Candidate
9
Administer aspirin
ED Arrival
60 min
Candidate
10
Review risks/benefits with patient and family: If acceptable —
• Give tPA
• No anticoagulants or antiplatelet treatment for 24 hours
11
• Begin stroke pathway
• Admit to stroke unit if available
• Monitor BP; treat if indicated
• Monitor neurologic status; emergent CT if deterioration
• Monitor blood glucose; treat if needed
• Initiate supportive therapy; treat comorbidities

Fig. 86.5 American Heart Association Algorithm for Suspected Stroke. *ABC*, Airway, breathing, circulation; *BP*, blood pressure; *CT*, computed tomography; *EMS*, emergency medical services; *IV*, intravenous. (From ECC Committee, Subcommittees and Task Forces of the American Heart Association: Part 9: Adult Stroke: 2005 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation*. 2005;112:IV-111–IV-120.)

by a prolonged PR interval (>0.20 second) and is generally benign. Second-degree AV block is divided into Mobitz types I and II. In Mobitz type I block, the block is at the AV node and is often transient and asymptomatic. In Mobitz type II block, the block is usually below the AV node within the His-Purkinje system; this block is often symptomatic, with the potential to progress to complete (third-degree) AV block. Third-degree AV block may occur at the AV node, bundle of His, or bundle branches. When third-degree AV block is present, the atria and ventricles are completely dissociated. Third-degree AV block can be permanent or transient, depending on the underlying cause.

Because hypoxemia is a common cause of bradycardia, initial evaluation of any patient with bradycardia should focus on signs of increased work of breathing (tachypnea, intercostal retractions, suprasternal retractions, paradoxical abdominal breathing) and oxygen saturation as determined by pulse oximetry. If oxygenation is inadequate or the patient shows signs of increased work of breathing, supplementary oxygen should be provided. A monitor should be attached to the patient for blood pressure, ECG, and oxygen saturation monitoring, and IV access should be established. If possible, obtain a 12-lead ECG to better define the rhythm. While initiating treatment, evaluate the patient's clinical status and identify potentially reversible causes.

The provider must identify signs and symptoms of poor perfusion and determine if those signs are likely to be caused by the bradycardia. If the signs and symptoms are not due to bradycardia, the provider should reassess the underlying cause of the patient's symptoms. Asymptomatic or minimally symptomatic patients do not necessarily require treatment unless there is suspicion that the rhythm is likely to progress to symptoms or more advanced bradyarrhythmias (e.g., Mobitz type II second-degree AV block in the setting of acute myocardial infarction). If the bradycardia is suspected to be the cause of acute altered mental status, ischemic chest discomfort, acute heart failure, hypotension, or other signs of shock, the patient should receive immediate treatment.

Atropine remains the first-line drug for acute symptomatic bradycardia. The recommended atropine dose for bradycardia is 0.5 mg IV every 3 to 5 minutes to a maximum total dose of 3 mg. Doses of atropine sulfate of less than 0.5 mg may result in paradoxical bradycardia. Atropine will also unlikely be effective in patients who had heart transplantation because the transplanted heart lacks vagal innervation. Since atropine works by reversing the muscarinic effects of the parasympathetic nervous system, it is not the preferred drug of choice for type II second-degree or third-degree AV block or in patients with third-degree AV block with a new wide-QRS complex where the location of block is likely to be more distal than the AV nodes. These bradyarrhythmias are not likely to be responsive to atropine and should be treated with transcutaneous pacing (TCP) or β-adrenergic agonists as temporizing measures while the patient is prepared for transvenous pacing.

If bradycardia is unresponsive to atropine, IV infusion of β-adrenergic agonists (dopamine, epinephrine) can be considered. Dopamine is a catecholamine with both α- and β-adrenergic actions. It can be titrated to more selectively target heart rate or vasoconstriction. At lower doses, dopamine has a more selective effect on inotropy and heart rate; at higher doses (>10 μg/kg/min), it also has vasoconstrictive effects. Epinephrine, as described previously, is a catecholamine with α- and β-adrenergic actions. Isoproterenol is a β-adrenergic agent with β-1 and β-2 effects, resulting in an increase in heart rate and vasodilation. The recommended adult dose is 2 to 10 μg/min by IV infusion, titrated to the appropriate heart rate and rhythm response.

TCP can be done through the multifunctional pacing/defibrillating pads. It is painful, and sedation should be considered in all awake patients. TCP should be considered a temporary measure only, and the patient should always be prepared for transvenous pacing. Expert consultation should be obtained as soon as possible. Transesophageal atrial pacing can be effective in treating intraoperative supraventricular bradyarrhythmias such as sinus or junctional bradycardia. This device is compatible with most external pacing devices and defibrillators. However, transesophageal pacing is only effective at pacing the atria, at least in its current configuration. In a patient who has AV conduction issues, such as complete heart block, this intervention is ineffective. Effective and consistent pacing also relies on normal acid-base status and electrolyte concentrations; thus acidemia and electrolyte abnormalities such as severe hyperkalemia need to be corrected if pacing is not successful.

Fig. 86.6 illustrates the bradyarrhythmias treatment algorithm recommended in the 2015 AHA Guidelines for CPR and ECC.

TACHYARRHYTHMIA

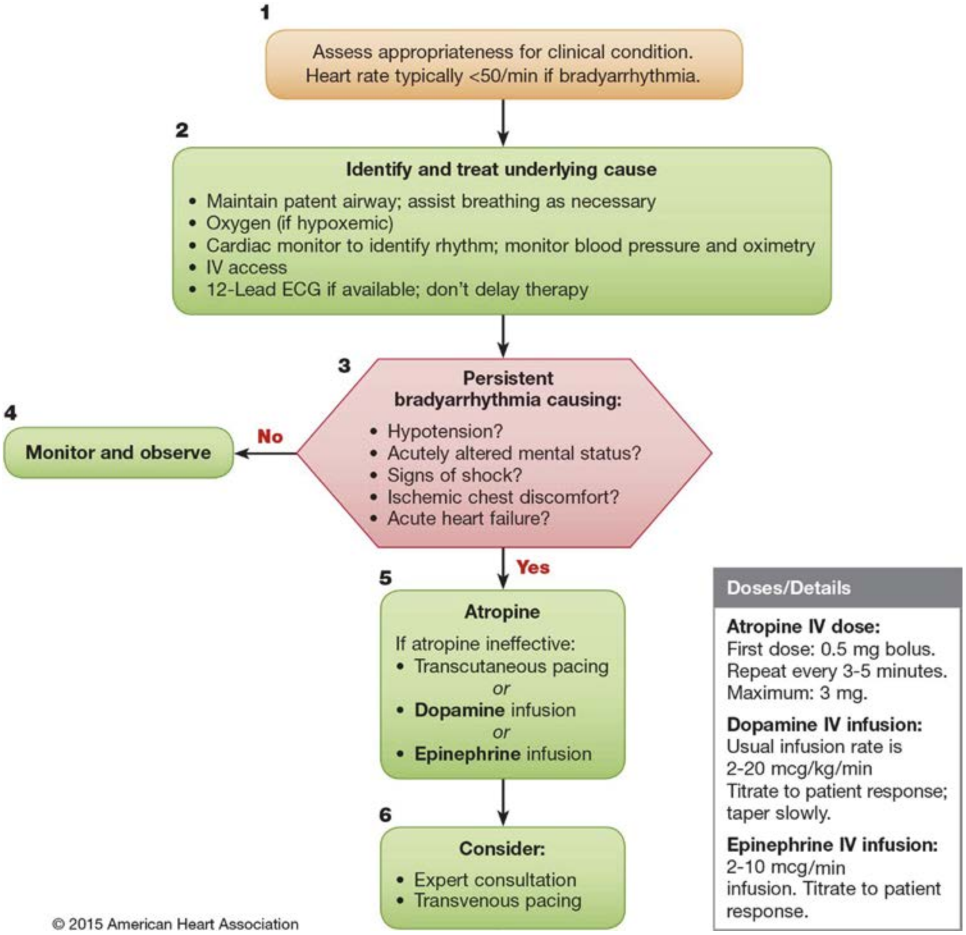
Tachyarrhythmia is defined as an arrhythmia with a rate of more than 100 beats/min, although, as with defining bradycardia, an arrhythmia rate of 150 or more beats/min is more likely to cause clinical symptoms. When encountering patients with tachycardia, efforts should be made to determine whether the tachycardia is the primary cause of the presenting symptoms, or secondary to an underlying condition that is causing both the presenting symptoms and the faster heart rate.

Tachycardia can be classified in several ways, based on the appearance of the QRS complex, heart rate, and regularity. Narrow-complex tachycardias (supraventricular tachycardia [SVT], QRS < 0.12 second) include sinus tachycardia, atrial fibrillation, atrial flutter, AV nodal reentry, accessory pathway–mediated tachycardia, atrial tachycardia (including automatic and reentry forms), multifocal atrial tachycardia, and junctional tachycardia. Wide–QRS-complex tachycardias (QRS ≥ 0.12 second) include VT and VF, SVT with aberrancy, preexcited tachycardias (Wolff-Parkinson-White syndrome), and ventricular-paced rhythms.

Because hypoxemia is a common cause of tachycardia, initial evaluation of any patient with tachycardia, similar to those with bradycardia, should focus on identifying signs of increased work of breathing and oxygen saturation. Patients should be closely monitored and supplemental oxygen provided. A 12-lead ECG better defines the rhythm, but the process should not delay immediate cardioversion if the patient is unstable.

If signs and symptoms persist despite provision of supplementary oxygen and support of airway and ventilation, the provider should assess the patient's degree of instability and determine if the instability is related to the tachycardia. If the patient demonstrates rate-related cardiovascular compromise with signs and symptoms such as acute altered mental status, ischemic chest discomfort, acute heart failure, hypotension, or other signs of shock suspected to be due to a tachyarrhythmia, the provider should proceed to immediate synchronized cardioversion, which can terminate tachyarrhythmias by interrupting the underlying reentrant pathway. The recommended initial biphasic energy dose for cardioversion of atrial fibrillation is 120 to 200 J. Cardioversion of atrial flutter and other SVTs generally requires less energy; an initial energy of 50 J to 100 J is often sufficient. If the initial 50 J shock fails, the provider should increase the dose in a stepwise fashion. Monomorphic VT with a pulse responds well to monophasic or biphasic waveform cardioversion (synchronized) shocks at initial energies of 100 J. If a patient has polymorphic VT, treat the rhythm as VF and deliver high-energy unsynchronized shocks (defibrillation doses).

If the patient with tachycardia is stable, then determine if the patient has a narrow-complex or wide-complex tachycardia, whether the rhythm is regular or irregular, and for wide complexes whether the QRS morphology is monomorphic or polymorphic. Therapy is then tailored accordingly. For regular narrow-complex SVT, vagal maneuvers such as carotid massage or Valsalva maneuver are used first to terminate the arrhythmia. If vagal maneuvers are unsuccessful, then adenosine is the drug of choice for terminating organized rapid supraventricular



1
Assess appropriateness for clinical condition.
Heart rate typically <50/min if bradyarrhythmia.
2
Identify and treat underlying cause
• Maintain patent airway; assist breathing as necessary
• Oxygen (if hypoxemic)
• Cardiac monitor to identify rhythm; monitor blood pressure and oximetry
• IV access
• 12-Lead ECG if available; don't delay therapy
3
Persistent bradyarrhythmia causing:
• Hypotension?
• Acutely altered mental status?
• Signs of shock?
• Ischemic chest discomfort?
• Acute heart failure?
No
4
Monitor and observe
Yes
5
Atropine
If atropine ineffective:
• Transcutaneous pacing
or
• Dopamine infusion
or
• Epinephrine infusion
6
Consider:
• Expert consultation
• Transvenous pacing
Doses/Details
Atropine IV dose:
First dose: 0.5 mg bolus.
Repeat every 3-5 minutes.
Maximum: 3 mg.
Dopamine IV infusion:
Usual infusion rate is
2-20 mcg/kg/min
Titrate to patient response;
taper slowly.
Epinephrine IV infusion:
2-10 mcg/min
infusion. Titrate to patient
response.

Fig. 86.6 2015 American Heart Association Adult Bradycardia With a Pulse Algorithm. *IV*, Intravenous. (From Link MS, Berkow LC, Kudenchuk PJ, et al. Part 7: Adult Advanced Cardiovascular Life Support: 2015 American Heart Association Guidelines Update for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation*. 2015;132[18 suppl 2]:S444–S464.)

arrhythmias. Adenosine slows sinoatrial and AV nodal conduction and prolongs refractoriness, which is very effective in terminating paroxysmal SVT (PSVT), the most common cause of which is reentry within the AV node. The drug is also used to diagnose the underlying mechanism in tachyarrhythmias of uncertain origin (e.g., atrial fibrillation, atrial flutter) by inducing transient block of AV nodal conduction. If adenosine or vagal maneuvers fail to convert PSVT, PSVT recurs after such treatment, or these treatments disclose a different form of SVT (such as atrial fibrillation or flutter), it is reasonable to use longer-acting AV nodal blocking agents, such as the nondihydropyridine calcium channel blockers (verapamil and diltiazem) or β-blockers.

Treatable causes of VT should always be sought before or during pharmacologic or electrical interventions. Hypoxemia, hypercapnia, hypokalemia or hypomagnesemia (or both), digitalis toxicity, and acid-base derangements are obvious causes for VT and should be quickly evaluated and corrected if present. If antiarrhythmic therapy is pursued, procainamide, amiodarone, or sotalol are recommended. Importantly, only one drug should be administered; a second drug should not be added without expert consultation. Hypotension is common with all three of these medications.

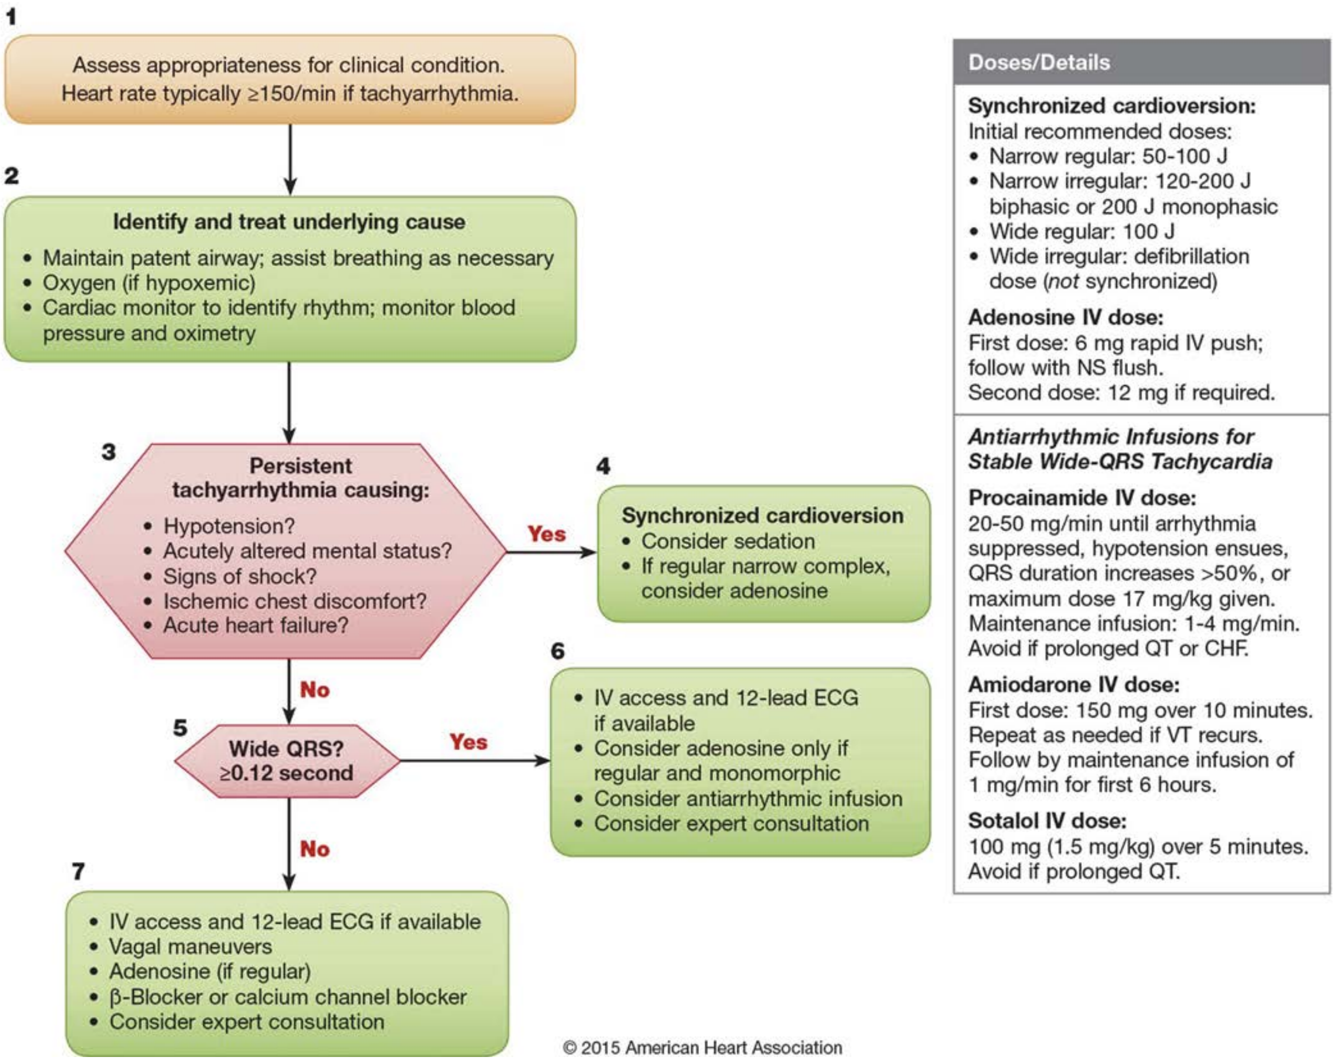
The evaluation and management of tachyarrhythmias is illustrated in the 2015 ACLS Tachycardia with Pulse Algorithm (Fig. 86.7). The medications used for tachyarrhythmia are listed in Tables 86.2 and 86.3.

Postresuscitation Interventions

Hypoxemia, ischemia, and reperfusion occurs during cardiac arrest and resuscitation, regardless of cause of cardiac arrest, and this may cause damage to multiple organ systems. Therefore, effective post–cardiac arrest care consists of identification and treatment of the precipitating cause of cardiac arrest combined with the assessment and mitigation of ischemia-reperfusion injury to multiple organ systems. The severity of damage can vary widely among patients and among organ systems within individual patients. Care must be tailored to the particular disease and dysfunction that affect each patient. Therefore, individual patients may require few, many, or all of the specific interventions discussed in the following part of this section.

EMERGENCY PERCUTANEOUS CORONARY INTERVENTION

Acute coronary syndromes are a common etiology for OHCA in adults with no obvious extracardiac cause of arrest and also can precipitate some IHCA. One study examined



1
Assess appropriateness for clinical condition.
Heart rate typically ≥150/min if tachyarrhythmia.
2
Identify and treat underlying cause
• Maintain patent airway; assist breathing as necessary
• Oxygen (if hypoxemic)
• Cardiac monitor to identify rhythm; monitor blood pressure and oximetry
3
Persistent tachyarrhythmia causing:
• Hypotension?
• Acutely altered mental status?
• Signs of shock?
• Ischemic chest discomfort?
• Acute heart failure?
Yes
4
Synchronized cardioversion
• Consider sedation
• If regular narrow complex, consider adenosine
No
5
Wide QRS? ≥0.12 second
Yes
6
• IV access and 12-lead ECG if available
• Consider adenosine only if regular and monomorphic
• Consider antiarrhythmic infusion
• Consider expert consultation
No
7
• IV access and 12-lead ECG if available
• Vagal maneuvers
• Adenosine (if regular)
• β-Blocker or calcium channel blocker
• Consider expert consultation
Doses/Details
Synchronized cardioversion:
Initial recommended doses:
• Narrow regular: 50-100 J
• Narrow irregular: 120-200 J biphasic or 200 J monophasic
• Wide regular: 100 J
• Wide irregular: defibrillation dose (not synchronized)
Adenosine IV dose:
First dose: 6 mg rapid IV push; follow with NS flush.
Second dose: 12 mg if required.
Antiarrhythmic Infusions for Stable Wide-QRS Tachycardia
Procainamide IV dose:
20-50 mg/min until arrhythmia suppressed, hypotension ensues, QRS duration increases >50%, or maximum dose 17 mg/kg given.
Maintenance infusion: 1-4 mg/min.
Avoid if prolonged QT or CHF.
Amiodarone IV dose:
First dose: 150 mg over 10 minutes.
Repeat as needed if VT recurs.
Follow by maintenance infusion of 1 mg/min for first 6 hours.
Sotalol IV dose:
100 mg (1.5 mg/kg) over 5 minutes.
Avoid if prolonged QT.

Fig. 86.7 2015 American Heart Association Adult Tachycardia With a Pulse Algorithm. *IV*, Intravenous; *NS*, normal saline; *VT*, ventricular tachycardia. (From Link MS, Berkow LC, Kudenchuk PJ, et al. Part 7: Adult Advanced Cardiovascular Life Support: 2015 American Heart Association Guidelines Update for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation*. 2015;132[18 suppl 2]:S444–S464.)

a consecutive series of post–cardiac arrest patients with suspected cardiovascular cause, and found a coronary artery lesion amenable to emergency treatment in 96% of patients with ST elevation and in 58% of patients without ST elevation during subsequent coronary angiography.[64] Thus urgent coronary angiography with prompt recanalization of any infarct-related artery is crucially important to improving the patient's survival, enhancing neurologic outcome, and preventing recurrence of arrest.

Evidence regarding the timing of coronary angiography immediately after cardiac arrest (defined variously, but within 24 hours) is limited to observational studies. Data from studies with more than 3800 patients having ST elevation on ECG after ROSC after cardiac arrest demonstrated a benefit of immediate coronary angiography with improved survival to hospital discharge, while more than half of these studies also demonstrated a benefit with improved neurological outcomes.[65-67] Fewer data are available to evaluate coronary angiography in patients without ST elevation on the initial post–cardiac arrest ECG. Two studies demonstrated a benefit with improved survival to hospital discharge and improved neurologic outcome when patients received immediate coronary angiography.[65,68] In these studies, the decision to undertake the intervention was influenced by a variety of factors such as patient age, duration of CPR, hemodynamic instability, presenting cardiac rhythm, neurologic status upon hospital arrival, and perceived likelihood of cardiac etiology. The 2015 AHA Guidelines for CPR and ECC recommended that coronary angiography should be performed emergently (rather than later in the hospital stay or not at all) for OHCA patients with suspected cardiac etiology of arrest and ST elevation on ECG. Emergency coronary angiography should be considered for select (e.g., electrically or hemodynamically unstable) adult patients who are comatose after OHCA of suspected cardiac origin but without ST elevation on ECG. Overall, coronary angiography is reasonable in post–cardiac arrest patients where coronary angiography is indicated, regardless of the patient's mental status. The 2015 acute coronary syndrome algorithm is illustrated in Fig. 86.8.[69]

TABLE 86.2 Summary of Medications Used for Supraventricular Tachycardia

Drug	Characteristics	Indication(s)	Dosing	Side Effects	Precautions or Special Considerations
Adenosine	Endogenous purine nucleoside; briefly depresses sinus node rate and AV node conduction; vasodilator	■ Stable, narrow-complex regular tachycardias ■ Unstable narrow-complex regular tachycardias while preparations are made for electrical cardioversion ■ Stable, regular, monomorphic, wide-complex tachycardia as a therapeutic and diagnostic maneuver	6 mg IV as a rapid IV push followed by a 20 mL saline flush; repeat if required as 12 mg IV push	Hypotension, bronchospasm, chest discomfort	Contraindicated in patients with asthma; may precipitate atrial fibrillation, which may be very rapid in patients with WPW; thus a defibrillator should be readily available; reduce dose in post–cardiac transplant patients, those taking dipyridamole or carbamazepine and when administered via a central vein
Diltiazem, Verapamil	Non-dihydropyridine calcium channel blockers; slow AV node conduction and increase AV node refractoriness; vasodilators, negative inotropes	■ Stable, narrow-complex tachycardias if rhythm remains uncontrolled or unconverted by adenosine or vagal maneuvers or if SVT is recurrent ■ Control ventricular rate in patients with atrial fibrillation or atrial flutter	Diltiazem: Initial dose 15-20 mg (0.25 mg/kg) IV over 2 min; additional 20-25 mg (0.35 mg/kg) IV in 15 min if needed; 5-15 mg/h IV maintenance infusion (titrated to AF heart rate if given for rate control) Verapamil: Initial dose 2.5-5 mg IV given over 2 min; may repeat as 5-10 mg every 15-30 min to total dose of 20-30 mg	Hypotension, bradycardia, precipitation of heart failure	Should only be given to patients with narrow-complex tachycardias (regular or irregular). Avoid in patients with heart failure and preexcited AF or flutter or rhythms consistent with VT
Atenolol, Esmolol, Metoprolol, Propranolol	β-Blockers; reduce effects of circulating catecholamines; reduce heart rate, AV node conduction and blood pressure; negative inotropes	■ Stable, narrow-complex tachycardias if rhythm remains uncontrolled or unconverted by adenosine or vagal maneuvers or if SVT is recurrent ■ Control ventricular rate in patients with atrial fibrillation or atrial flutter ■ Certain forms of polymorphic VT (associated with acute ischemia, familial LQTS, catecholaminergic)	Atenolol (β1 specific blocker) 5 mg IV over 5 min; repeat 5 mg in 10 min if arrhythmia persists or recurs Esmolol (β1 specific blocker with 2- to 9-min half-life) IV loading dose 500 mcg/kg (0.5 mg/kg) over 1 min, followed by an infusion of 50 mcg/kg per min (0.05 mg/kg/min); if response is inadequate, infuse second loading bolus of 0.5 mg/kg over 1 min and increase maintenance infusion to 100 mcg/kg (0.1 mg/kg) per min; increment; increase in this manner if required to maximum infusion rate of 300 mcg/kg [0.3 mg/kg] per min Metoprolol (β1 specific blocker) 5 mg over 1-2 min repeated as required every 5 min to maximum dose of 15 mg Propranolol (nonselective β-blocker) 0.5-1 mg over 1 min, repeated up to a total dose of 0.1 mg/kg if required	Hypotension, bradycardia, precipitation of heart failure	Avoid in patients with asthma, obstructive airway disease, decompensated heart failure and pre-excited atrial fibrillation or flutter
Procainamide	Sodium and potassium channel blocker	■ Preexcited atrial fibrillation	20-50 mg/min until arrhythmia suppressed, hypotension ensues, or QRS prolonged by 50%, or total cumulative dose of 17 mg/kg; or 100 mg every 5 min until arrhythmia is controlled or other conditions described above are met	Bradycardia, hypotension, torsades de pointes	Avoid in patients with QT prolongation and CHF
Amiodarone	Multichannel blocker (sodium, potassium, calcium channel, and noncompetitive α/β-blocker)	■ Stable irregular narrow-complex tachycardia (atrial fibrillation) ■ Stable regular narrow-complex tachycardia ■ To control rapid ventricular rate due to accessory pathway conduction in pre-excited atrial arrhythmias	150 mg given over 10 min and repeated if necessary, followed by a 1 mg/min infusion for 6 h, followed by 0.5 mg/min. Total dose over 24 h should not exceed 2.2 g.	Bradycardia, hypotension, phlebitis

TABLE 86.3 Summary of Medications Used for Ventricular Tachycardia

Drug	Characteristics	Indication(s)	Dosing	Side Effects	Precautions or Special Considerations
Procainamide	Sodium and potassium channel blocker	▪ Hemodynamically stable monomorphic VT	20-50 mg/min until arrhythmia suppressed, hypotension ensues, or QRS prolonged by 50%, or total cumulative dose of 17 mg/kg; or 100 mg every 5 min until arrhythmia is controlled or other conditions described previously are met	Bradycardia, hypotension, torsades de pointes	Avoid in patients with QT prolongation and CHF
Amiodarone	Multichannel blocker (sodium, potassium, calcium channel, α- and noncompetitive β-blocker)	▪ Hemodynamically stable monomorphic VT ▪ Polymorphic VT with normal QT interval	150 mg given over 10 min and repeated if necessary, followed by a 1 mg/min infusion for 6 h, followed by 0.5 mg/min. Total dose over 24 h should not exceed 2.2 g.	Bradycardia, hypotension, phlebitis	
Sotalol	Potassium channel blocker and nonselective β-blocker	▪ Hemodynamically stable monomorphic VT	In clinical studies 1.5 mg/kg infused over 5 min; however, U.S. package labeling recommends any dose of the drug should be infused slowly over a period of 5 h	Bradycardia, hypotension, torsades de pointes	Avoid in patients with QT prolongation and CHF
Lidocaine	Relatively weak sodium channel blocker	▪ Hemodynamically stable monomorphic VT	Initial dose range from 1 to 1.5 mg/kg IV; repeated if required at 0.5-0.75 mg/kg IV every 5-10 min up to maximum cumulative dose of 3 mg/kg; 1-4 mg/min (30-50 mcg/kg/min) maintenance infusion	Slurred speech, altered consciousness, seizures, bradycardia	
Magnesium	Cofactor in variety of cell processes including control of sodium and potassium transport	▪ Polymorphic VT associated with QT prolongation (torsades de pointes)	1-2 g IV over 15 min	Hypotension, CNS toxicity, respiratory depression	Follow magnesium levels if frequent or prolonged dosing required, particularly in patients with impaired renal function

CHF, Congestive heart failure; *CNS,* central nervous system; *IV*, intravenous; *VT*, ventricular tachycardia.

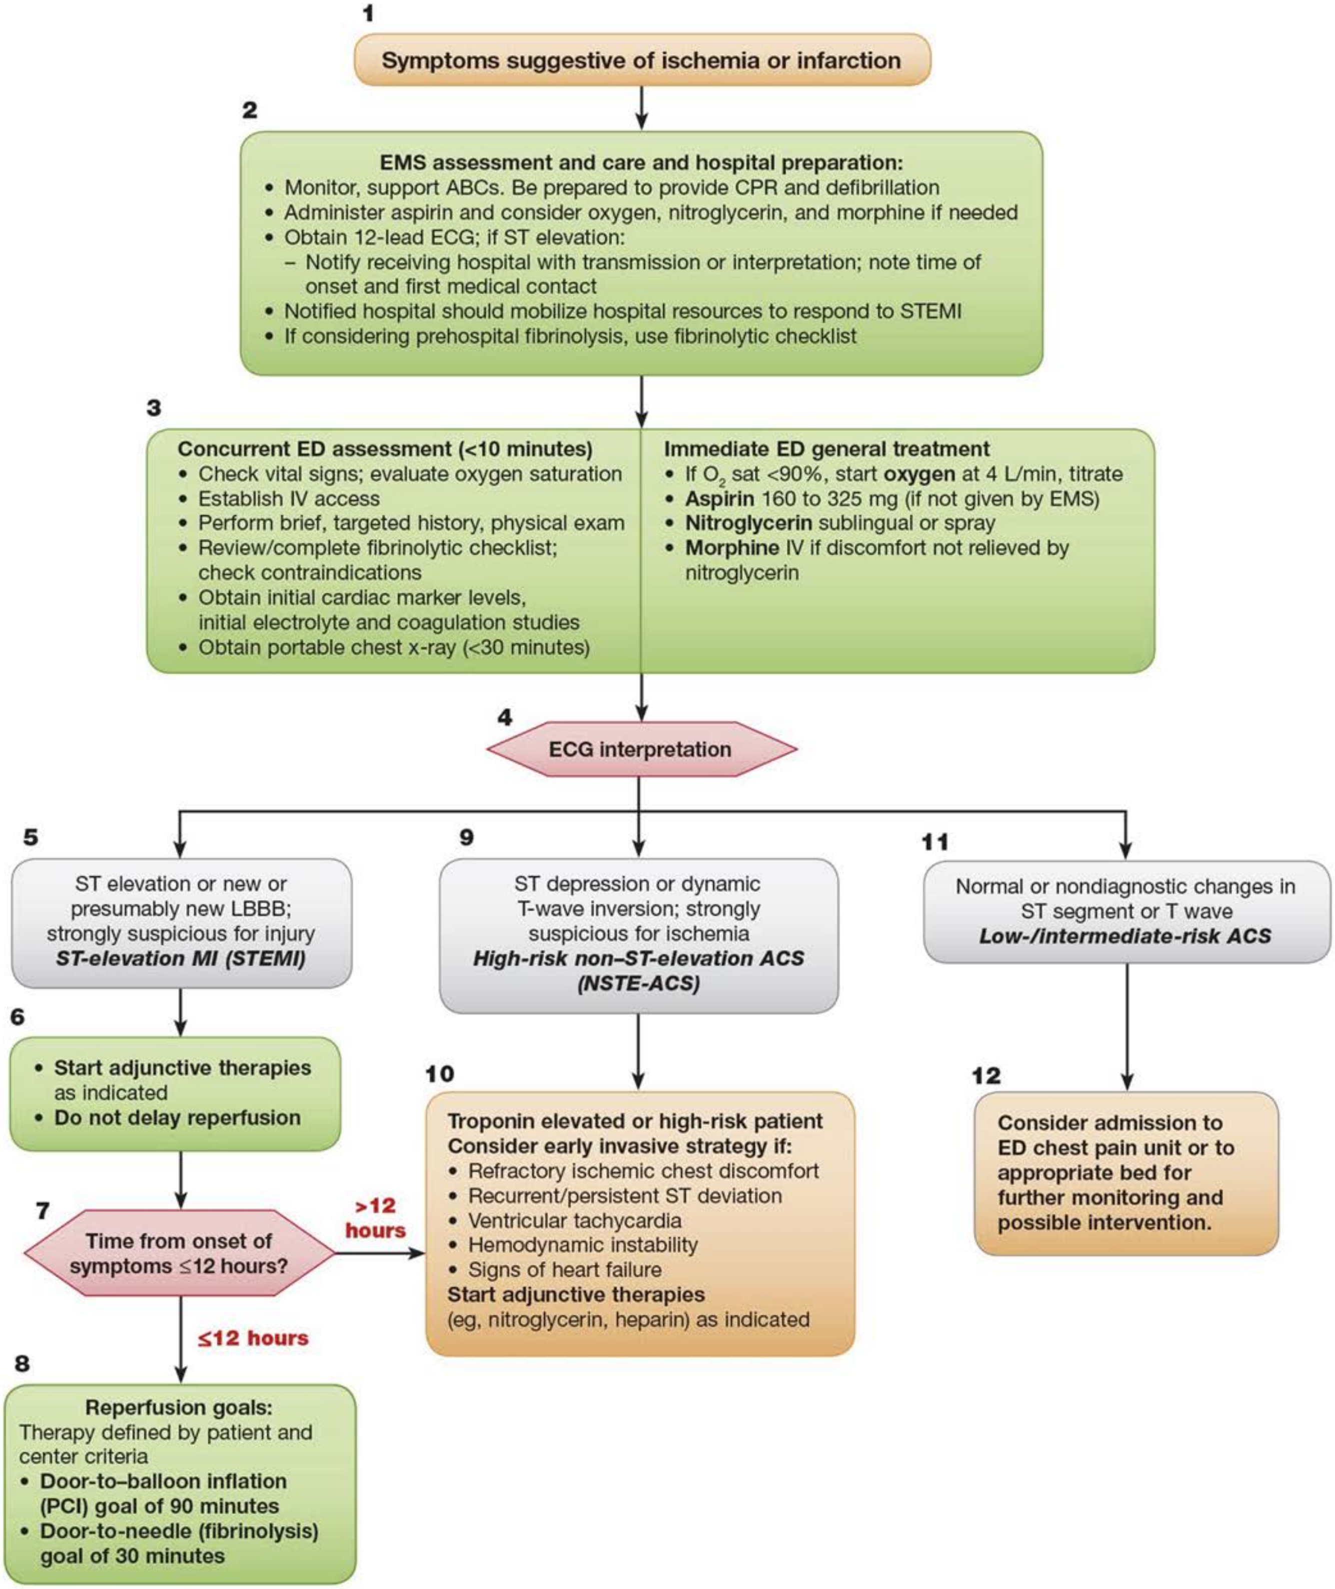
TARGETED TEMPERATURE MANAGEMENT

Devastating neurologic injury, particularly anoxic brain injury, is frequent in post–cardiac arrest patients. Over the years, numerous pharmacologic interventions, including steroids, barbiturates, and nimodipine, have been tried for cerebral protection in this patient population with unsatisfactory results. This was until the seminal publications describing the use of systemic hypothermia to 33°C within 2 hours of OHCA and maintained for 12 or 24 hours, which showed improved outcomes among survivors.[70,71] The mechanism of cerebral protection with hypothermia is complex, but is suggested to include its effect on the cerebral metabolic rate. For every 1°C reduction in brain temperature, a 6% reduction in cerebral metabolic rate is



1
Symptoms suggestive of ischemia or infarction
2
EMS assessment and care and hospital preparation:
• Monitor, support ABCs. Be prepared to provide CPR and defibrillation
• Administer aspirin and consider oxygen, nitroglycerin, and morphine if needed
• Obtain 12-lead ECG; if ST elevation:
– Notify receiving hospital with transmission or interpretation; note time of onset and first medical contact
• Notified hospital should mobilize hospital resources to respond to STEMI
• If considering prehospital fibrinolysis, use fibrinolytic checklist
3
Concurrent ED assessment (<10 minutes)
• Check vital signs; evaluate oxygen saturation
• Establish IV access
• Perform brief, targeted history, physical exam
• Review/complete fibrinolytic checklist; check contraindications
• Obtain initial cardiac marker levels, initial electrolyte and coagulation studies
• Obtain portable chest x-ray (<30 minutes)
Immediate ED general treatment
• If O_2 sat <90%, start oxygen at 4 L/min, titrate
• Aspirin 160 to 325 mg (if not given by EMS)
• Nitroglycerin sublingual or spray
• Morphine IV if discomfort not relieved by nitroglycerin
4
ECG interpretation
5
ST elevation or new or presumably new LBBB; strongly suspicious for injury
ST-elevation MI (STEMI)
9
ST depression or dynamic T-wave inversion; strongly suspicious for ischemia
High-risk non–ST-elevation ACS (NSTE-ACS)
11
Normal or nondiagnostic changes in ST segment or T wave
Low-/intermediate-risk ACS
6
• Start adjunctive therapies as indicated
• Do not delay reperfusion
7
Time from onset of symptoms ≤12 hours?
>12 hours
≤12 hours
8
Reperfusion goals:
Therapy defined by patient and center criteria
• Door-to–balloon inflation (PCI) goal of 90 minutes
• Door-to-needle (fibrinolysis) goal of 30 minutes
10
Troponin elevated or high-risk patient
Consider early invasive strategy if:
• Refractory ischemic chest discomfort
• Recurrent/persistent ST deviation
• Ventricular tachycardia
• Hemodynamic instability
• Signs of heart failure
Start adjunctive therapies
(eg, nitroglycerin, heparin) as indicated
12
Consider admission to ED chest pain unit or to appropriate bed for further monitoring and possible intervention.

Fig. 86.8 **2015 American Heart Association Acute Coronary Syndrome Algorithm. *ABC*, Airway, breathing, circulation; *CPR*, cardiopulmonary resuscitation; *EMS*, emergency medical services; *IV*, intravenous.** (From O'Connor RE, Al Ali AS, Brady WJ, et al. Part 9: Acute Coronary Syndromes: 2015 American Heart Association Guidelines Update for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation*. 2015;132[18 suppl 2]:S483–S500. https://eccguidelines.heart.org/index.php/circulation/cpr-ecc-guidelines-2/part-9-acute-coronary-syndromes/.)

observed. By limiting the metabolic demand and decreasing the utilization of oxygen and glucose, targeted temperature management (TTM) reduces the risk of energy depletion, preserving the ion channel's integrity and decreasing the intracellular calcium influx that can trigger neuronal apoptotic pathways.[72] Indeed, animal models have been used to evaluate the mitigating effects of hypothermia on pathways leading to excitotoxicity, apoptosis, inflammation, and free radical production, as well as its significance in preserving the blood–brain barrier integrity, neuronal viability, and neurologic outcome.[73] TTM encompasses therapeutic hypothermia, controlled normothermia, and treatment of fever.

The HACA trial was the first study to show clinical benefit in a focused patient cohort.[71] Following the publication of this study, a number of other studies also evaluated induced hypothermia after cardiac arrest, which gained widespread use and is now advocated by international guidelines. Of note, the Target Temperature Management After Cardiac Arrest (or the TTM) trial[74] found no difference in neurologic outcome when comparing 939 OHCA victims after cooling to 33°C versus controlled temperature maintenance at 36°C, but both arms of this trial involved a form of TTM as opposed to no TTM. Consequently, the TTM trial might underscore the importance of active temperature management after ROSC. The 2015 AHA Guidelines for CPR and ECC recommend TTM in all comatose (i.e., lack of meaningful response to verbal commands) adult patients with ROSC after cardiac arrest, irrespective of the initial rhythm (shockable or not). A target temperature between 32°C and 36°C is recommended for at least 24 hours. It is also recommended to continue to monitor the temperature and maintain normothermia (treat fever) beyond this window. Prognostication should not occur until 72 hours after ROSC, or if TTM is provided, 72 hours after completion of TTM.

Experimental studies also suggest that the greatest benefit of hypothermia in neuroprotection is achieved when it is effectively applied within hours of the event, with likely benefit being within 6 hours or earlier after the insult. Although human studies have yet not confirmed the critical window for effective implementation of TTM to improve neurologic outcome after cardiac arrest, they have established that the target temperature is more rapidly obtained in cohorts where intranasal, surface, or intravascular temperature-modulating devices (servo-controlled or inbuilt feedback mechanisms) were used, as compared to surface cooling with air-cooling blankets, cooling fans, or ice cooling packs. There was also a lower likelihood to overshoot the target temperature when these devices were employed. Intravascular heat exchange catheters are currently the most efficient technique for achieving the target temperature within a short period after ROSC, and can also be used in combination with surface-cooling modalities.[75] Their use is nevertheless limited by their invasive nature and associated risks such as vascular injury, bleeding, or thrombosis. In addition, no benefit in survival has been shown using these more invasive devices. The use of cold saline as an adjunctive therapy in the prehospital setting is not recommended because the data from the RINSE trial showed that prehospital cold IV fluids in victims of cardiac arrest did not improve outcome, but resulted in an increased incidence of pulmonary edema during the first 24 hours after ROSC.[76]

POSTRESUSCITATION OXYGEN AND VENTILATION THERAPY

Hyperoxia in preclinical studies was associated with worsening oxidative stress, free radical production, and worsened organ function.[77] Importantly, Kilgannon and colleagues reported an association between hyperoxia and in-hospital mortality after resuscitation from cardiac arrest.[78] Consequently, the AHA guidelines recommend that once reliable oxygenation and ventilation monitors are in place, the fraction of inspired oxygen (FiO_2) should be decreased to avoid hyperoxia.[69,77] It is worth noting that in the immediate post-ROSC period, the intense systemic vasoconstriction may make it challenging for pulse oximetry to work optimally; thus access and use of arterial blood gases to guide therapy should be part of the management strategy.

Post–cardiac arrest patients are at increased risk for developing ARDS. Some of the contributing factors include aspiration pneumonia, pulmonary contusions after aggressive CPR, ventilator-associated lung injury, and the pulmonary manifestations of the post–cardiac arrest syndrome. The optimal mechanical ventilation strategy after cardiac arrest has, nevertheless, not been well defined. Although more focused studies are still needed, it is suggested that patients with ARDS should be ventilated according to the Acute Respiratory Distress Syndrome Network (ARDSNet) low-tidal volume strategy.[79]

Excessive hyperventilation and hypocarbia can also adversely affect the outcome, as it can lead to cerebral vasoconstriction and worsening blood flow, in particular in areas with no reflow or hypoperfusion after ROSC. A recent systematic review evaluating data from at least eight studies found that both hypocarbia and hypercarbia are associated with worse neurologic outcomes in the post–cardiac arrest syndrome patient.[23] Therefore, it is recommended that after resuscitation from cardiac arrest, the $PaCO_2$ be maintained within the normal physiologic range (end-tidal CO_2 30-40 mm Hg or $PaCO_2$ 35-45 mm Hg), taking into account any temperature correction.[69]

GLYCEMIC CONTROL IN THE POST–CARDIAC ARREST PATIENT

Hyperglycemia is frequently encountered in survivors of cardiac arrest because of a combination of several factors including the effect of counter-regulatory hormones in the immediate post-ROSC period. Poor glycemic control has been associated with poor neurologic outcome in critically ill patients. Hyperglycemia is thought to cause secondary injury by exacerbating intracellular acidosis, increasing free radical formation, increasing extracellular glutamate levels, and disrupting the blood–brain barrier. On the other hand, tight glucose control at low levels has also been associated with increased frequency of hypoglycemic episodes and poor patient outcome.[80] Although the data on glycemic control in the post-cardiac arrest patient are not definitive, it is reasonable to monitor blood glucose concentration and avoid extreme levels of blood glucose in this population.

DETERMINE THE CAUSE AND EXTENT OF INJURY AFTER CARDIAC ARREST

Laboratory Testing

Laboratory testing may provide insight into the etiology of cardiac arrest, help identify potentially reversible and/or intervenable factors, and may allow the evaluation of the extent of end-organ damage. In addition to the standard laboratory tests such as a complete blood count, electrolyte and lactate levels, arterial blood gases, and cardiac enzymes, it is reasonable to obtain a repeat ECG to identify ischemic changes and direct management toward emergency reperfusion therapy. Arrhythmias are not unusual in the post–cardiac arrest patient and, if not managed appropriately, may place the patient at risk for recurrent arrest. It is worth noting that besides coronary ischemia etiology, cardiomyopathies and electrical conduction abnormalities constitute the major etiologies for cardiac arrest. A prolonged QTc interval may reflect a primary arrhythmia such as Brugada syndrome, congenital QT prolongation syndromes, or a multitude of acquired etiologies of prolonged QTc in critically ill patients, including medications, hypothermia, electrolyte abnormalities, and bradycardia. In select patients, toxicology testing may be of value to rule out cocaine or methamphetamine intoxication. Cardiopulmonary collapse may also be precipitated by overdose of antidepressants, sedatives, and opioids, leading to profound hypoxemia triggering cardiac arrest.

Chest Radiographs

The value attributed to the diagnostic yield of chest radiographs has diminished over the past decade. However, radiographs can be valuable for rapid diagnosis of conditions such as a pneumothorax, or for confirmation of the position of the ETT and central venous catheters. Lung parenchymal pathology and mediastinal pathology should prompt other imaging modalities, such as computed tomography (CT) imaging.

Computed Tomography Imaging

CT imaging can be valuable to determine if pulmonary embolus is present and to examine the presence and extent of pulmonary aspiration or edema after resuscitation from cardiac arrest. CT imaging of the brain can also help identify the presence of intracranial hemorrhage, larger areas of cerebral ischemia, or cerebral edema.

Magnetic Resonance Imaging of the Brain

The role of magnetic resonance imaging (MRI) in the evaluation of the post–cardiac arrest patient is discussed in this section.

Echocardiography and Critical Care Ultrasonography

The widespread availability of echocardiographic equipment and its proficient use in intensive care have enabled early identification of important treatable causes of cardiac arrest. Examples include:

- Pericardial tamponade. It is worth noting that the size of pericardial effusion, which is a relatively common finding, is not diagnostic of tamponade, as the rate of fluid accumulation is more likely to determine tamponade pathophysiology. Usually the chamber with the lowest pressure, the right atrium, begins to collapse during ventricular diastole and can be visualized by echocardiography at the time of diagnosis.
- Acute myocardial ischemia with new regional wall motional abnormalities.
- Acute PE. Echocardiography can be very useful in the early diagnosis of PE, especially when the patient is too unstable to be transported for CT scans. Important echocardiographic findings include the demonstration of the McConnell sign (akinesia of the mid free wall but normal motion at the RV apex) or other RV strain patterns such as an RV diameter greater than 30 mm in the parasternal long-axis view, or an increase in the area of the RV relative to the LV in the apical four-chamber view. Flattening of the interventricular septum is another feature (D-shaped septum) that suggests the diagnosis of acute massive PE.
- Tension pneumothorax. Ultrasonography offers a higher sensitivity to the detection of an otherwise clinical diagnosis of tension pneumothorax. The quick demonstration of the "seashore sign," "B-lines," comet tails, and the "lung pulse" confirms the apposition of the visceral and parietal pleura and excludes pneumothorax.
- Severe hypovolemia. Inadequate circulating intravascular volume is frequently a precipitating cause of cardiac arrest of nonmyocardial etiology. Ultrasound/echocardiography allows for rapid evaluation of intravascular fluid status and response to a fluid challenge to guide management in the post–cardiac arrest patient. However, one has to be aware of the pitfalls of assessing volume status based on static indices.

TERMINATION OF RESUSCITATION EFFORTS—INDICATORS OF POOR OUTCOME POST-RETURN OF SPONTANEOUS CIRCULATION

The 2015 AHA Guidelines for CPR and ECC discussed the use of clinical examination, electrophysiologic measurements, imaging studies, and evaluation of blood or cerebrospinal fluid markers of brain injury to estimate the prognosis for neurologic improvement in patients who are comatose after cardiac arrest and the decision to terminate resuscitative efforts. Because sedatives or neuromuscular blockers received during TTM may be metabolized more slowly in post–cardiac arrest patients, and injured brains may be more sensitive to the depressant effects of various medications, residual sedation or paralysis can confound the accuracy of clinical examinations. Multiple investigations suggest that it is necessary to wait to prognosticate for a minimum of 72 hours after ROSC to minimize the rate of false-positive results in patients who had not undergone TTM and to wait for some period of time after return of normothermia for those using TTM. In many cases, clinicians choose to complete their final evaluation for prognostication 5 to 7 days after the arrest.

Studies have shown that factors such as the patient's prearrest comorbidities are associated with poor survival and outcome. The initial cardiac rhythm, the no-flow (arrest) and low-flow (CPR) times, and the quality of chest compressions (as indicated by the $ETCO_2$) are also associated with patient outcome. Clinical examinations, such as loss of corneal and pupillary light reflexes, extensor posturing, and the presence of status myoclonus, also point to a poor prognosis. In comatose patients who are treated with TTM or not, the absence of pupillary reflex to light at 72 hours or more after cardiac arrest has the lowest false-positive rate (FPR) of 0% to 1% to predict poor neurologic outcome compared with other clinical examination indicators.[69] It is also important to distinguish myoclonus from status myoclonus (continuous, repetitive myoclonic jerks lasting more than 30 minutes) because the presence of any myoclonus is not a reliable predictor of poor functional recovery, but status myoclonus during the first 72 hours after cardiac arrest achieved an FPR of 0%.[69]

EEG has been used widely in the diagnosis of seizures and prognostication after cardiac arrest, even though the lack of standardized EEG terminology continues to limit its use in research and practice. In comatose post–cardiac arrest patients who are treated with TTM, persistent absence of EEG reactivity to external stimuli at 72 hours after cardiac arrest and persistent burst suppression on EEG after rewarming, has a FPR of 0%. Intractable and persistent (more than 72 hours) status epilepticus in the absence of EEG reactivity to external stimuli is also an indicator of poor outcome. In comatose post–cardiac arrest patients who are not treated with TTM, the presence of burst suppression on EEG at 72 hours or more after cardiac arrest, in combination with other predictors, has a FPR of 0%, and can be used to predict poor outcome. In patients who are comatose after resuscitation from cardiac arrest regardless of treatment with TTM, bilateral absence of the N20 somatosensory-evoked potentials wave 24 to 72 hours after cardiac arrest or after rewarming predicts poor outcome (FPR 1%).

Brain imaging studies, including CT or MRI scans, can define structural brain injury or detect focal injury. In patients who are comatose after resuscitation from cardiac arrest and not treated with TTM, the presence of a marked reduction of the gray-white ratio on brain CT obtained within 2 hours after cardiac arrest could be used to predict poor outcome, as well as extensive restriction of diffusion on brain MRI at 2 to 6 days after cardiac arrest. However, it needs to be noted that both imaging modalities have higher FPRs and wider confidence intervals compared with clinical examination predictors, and thus should be used in combination with other established predictors to predict a poor neurologic outcome. There is currently no established role of laboratory biomarkers of brain injury in predicting neurologic outcome.

Pediatric Resuscitation

Pediatric cardiac arrest portends similar poor prognosis as adults. Data from the 2005 to 2007 Resuscitation Outcomes Consortium, a registry of 11 U.S. and Canadian emergency medical systems, showed age-dependent discharge survival rates of 3.3% for infants (younger than 1 year), 9.1% for children (1-11 years), and 8.9% for adolescents (12-19 years).[81] More recently, published data from this network demonstrated 8.3% survival to hospital discharge across all age groups.[82] Outcomes from pediatric IHCA, however, have markedly improved over the past decade. From 2001 to 2009, rates of pediatric IHCA survival to hospital discharge improved from 24% to 39%.[83] Prolonged CPR is not always futile, with 12% of patients who receive CPR for more than 35 minutes surviving to discharge and 60% of those survivors having a favorable neurologic outcome.[84] This improvement in survival rate from IHCA can be attributed to multiple factors, including emphasis on high-quality CPR and advances in postresuscitation care.

Pediatric resuscitation requires clinical expertise including understanding of its unique pathophysiology, clinical implications, and therapeutic considerations. Even though asphyxiation is the leading cause of pediatric cardiac arrest and warrants initial focused investigation and management, the pediatric resuscitation guidelines closely follow the adult guidelines in order to facilitate training, retention, and implementation of resuscitation guidelines. For example, minimally interrupted and effectively performed chest compressions, ventilation, and prompt defibrillation are emphasized to improve outcome from cardiac arrest and should always be the focus of resuscitation effort.

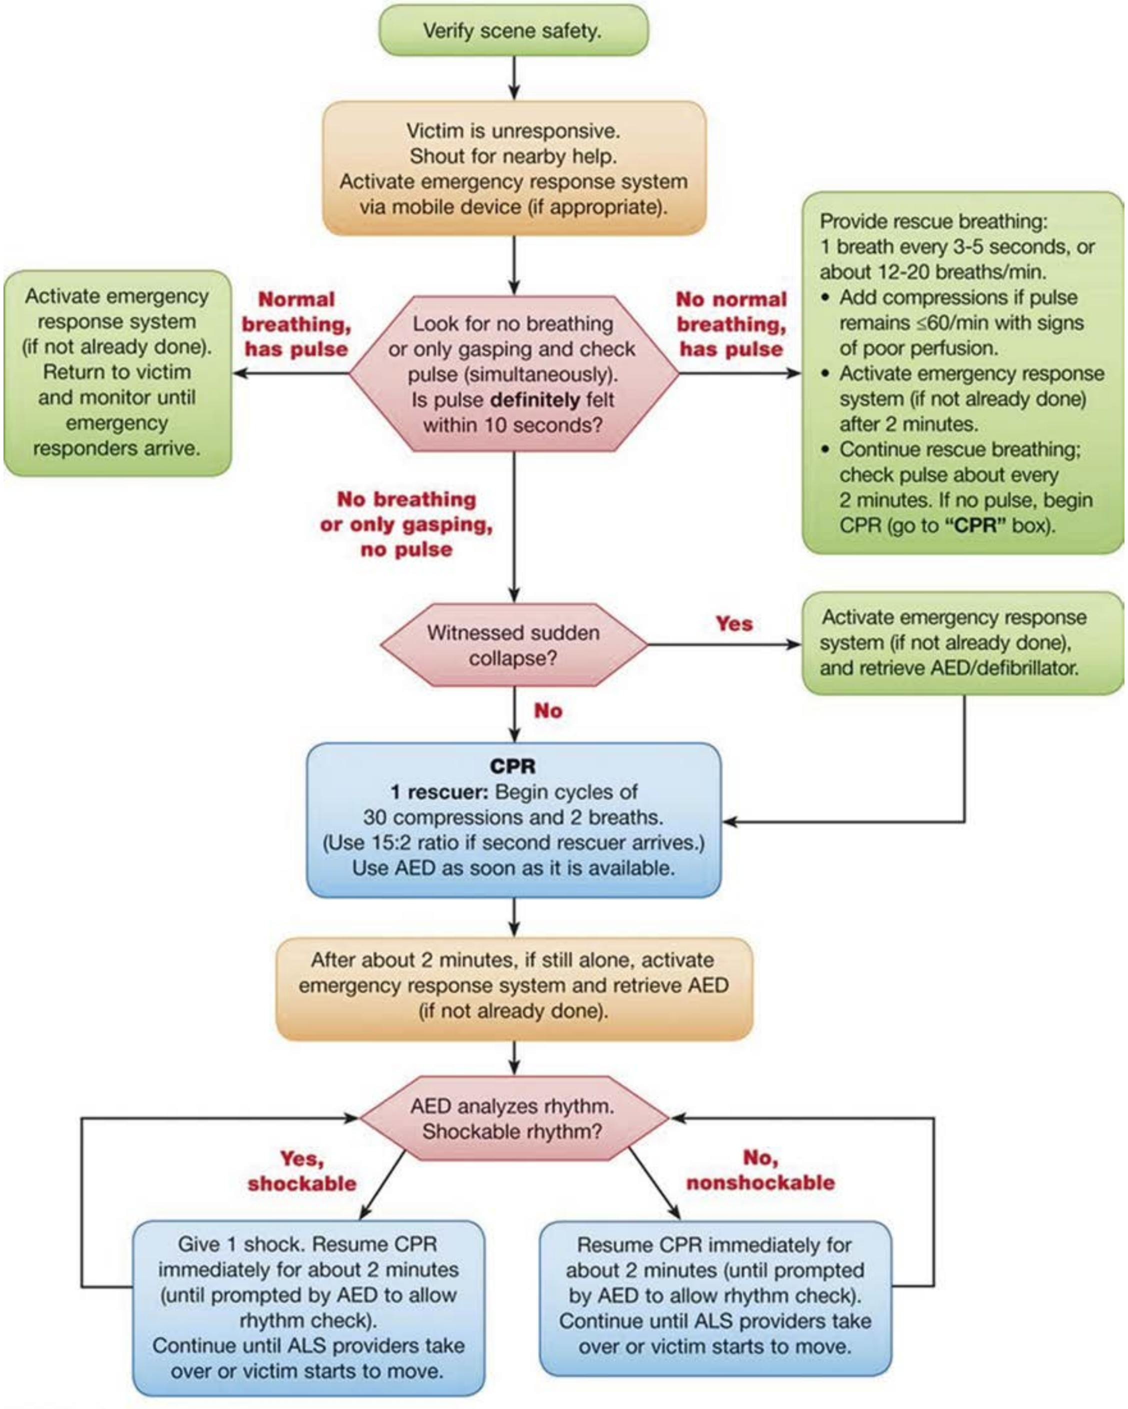
PEDIATRIC BASIC LIFE SUPPORT

Asphyxiation is a much more common cause of cardiac arrest in infants and children than a primary cardiac event, and airway management and ventilation are therefore more important during the resuscitation of children. Data from animal studies[85,86] and pediatric studies[87,88] suggest that resuscitation outcomes for asphyxial cardiac arrest are better with a combination of ventilation and chest compressions. Therefore, historically, the preferred sequence of CPR was A-B-C (Airway-Breathing-Circulation). However, a universal CPR algorithm for victims of all ages minimizes the complexity of CPR and offers consistency in CPR training. In addition, there is inadequate data to identify which resuscitation method offers better survival in this population: beginning with ventilations (A-B-C) first or with chest compressions (C-A-B). The 2015 AHA Guidelines for CPR and ECC maintained the changes of the 2010 recommendations that the C-A-B sequence should be used to decrease the time to initiation of chest compressions and reduce “no blood flow” time in acute pediatric cardiac arrest.

The 2015 AHA Guidelines for CPR and ECC on pediatric BLS algorithms separated one-person from two-person or more healthcare provider CPR to better guide rescuers through the initial stages of resuscitation (Figs. 86.9 and 86.10).[89] In an era where cellular telephones with speakers are common, this technology can allow a single rescuer to activate the emergency response system while beginning CPR. These algorithms continue to emphasize the importance of obtaining an AED quickly in a sudden, witnessed collapse, because such an event is likely to have a cardiac etiology.

The 2015 AHA Guidelines for CPR and ECC on pediatric BLS continue to emphasize the five components of high-quality CPR, which includes:

- Ensuring chest compressions of adequate rate
- Ensuring chest compressions of adequate depth
- Allowing full chest recoil between compressions
- Minimizing interruptions in chest compressions
- Avoiding excessive ventilation



Verify scene safety.
Victim is unresponsive. Shout for nearby help. Activate emergency response system via mobile device (if appropriate).
Activate emergency response system (if not already done). Return to victim and monitor until emergency responders arrive.
Normal breathing, has pulse
Look for no breathing or only gasping and check pulse (simultaneously). Is pulse definitely felt within 10 seconds?
No normal breathing, has pulse
Provide rescue breathing: 1 breath every 3-5 seconds, or about 12-20 breaths/min.
• Add compressions if pulse remains ≤60/min with signs of poor perfusion.
• Activate emergency response system (if not already done) after 2 minutes.
• Continue rescue breathing; check pulse about every 2 minutes. If no pulse, begin CPR (go to "CPR" box).
No breathing or only gasping, no pulse
Witnessed sudden collapse?
Yes
Activate emergency response system (if not already done), and retrieve AED/defibrillator.
No
CPR
1 rescuer: Begin cycles of 30 compressions and 2 breaths. (Use 15:2 ratio if second rescuer arrives.) Use AED as soon as it is available.
After about 2 minutes, if still alone, activate emergency response system and retrieve AED (if not already done).
AED analyzes rhythm. Shockable rhythm?
Yes, shockable
No, nonshockable
Give 1 shock. Resume CPR immediately for about 2 minutes (until prompted by AED to allow rhythm check). Continue until ALS providers take over or victim starts to move.
Resume CPR immediately for about 2 minutes (until prompted by AED to allow rhythm check). Continue until ALS providers take over or victim starts to move.

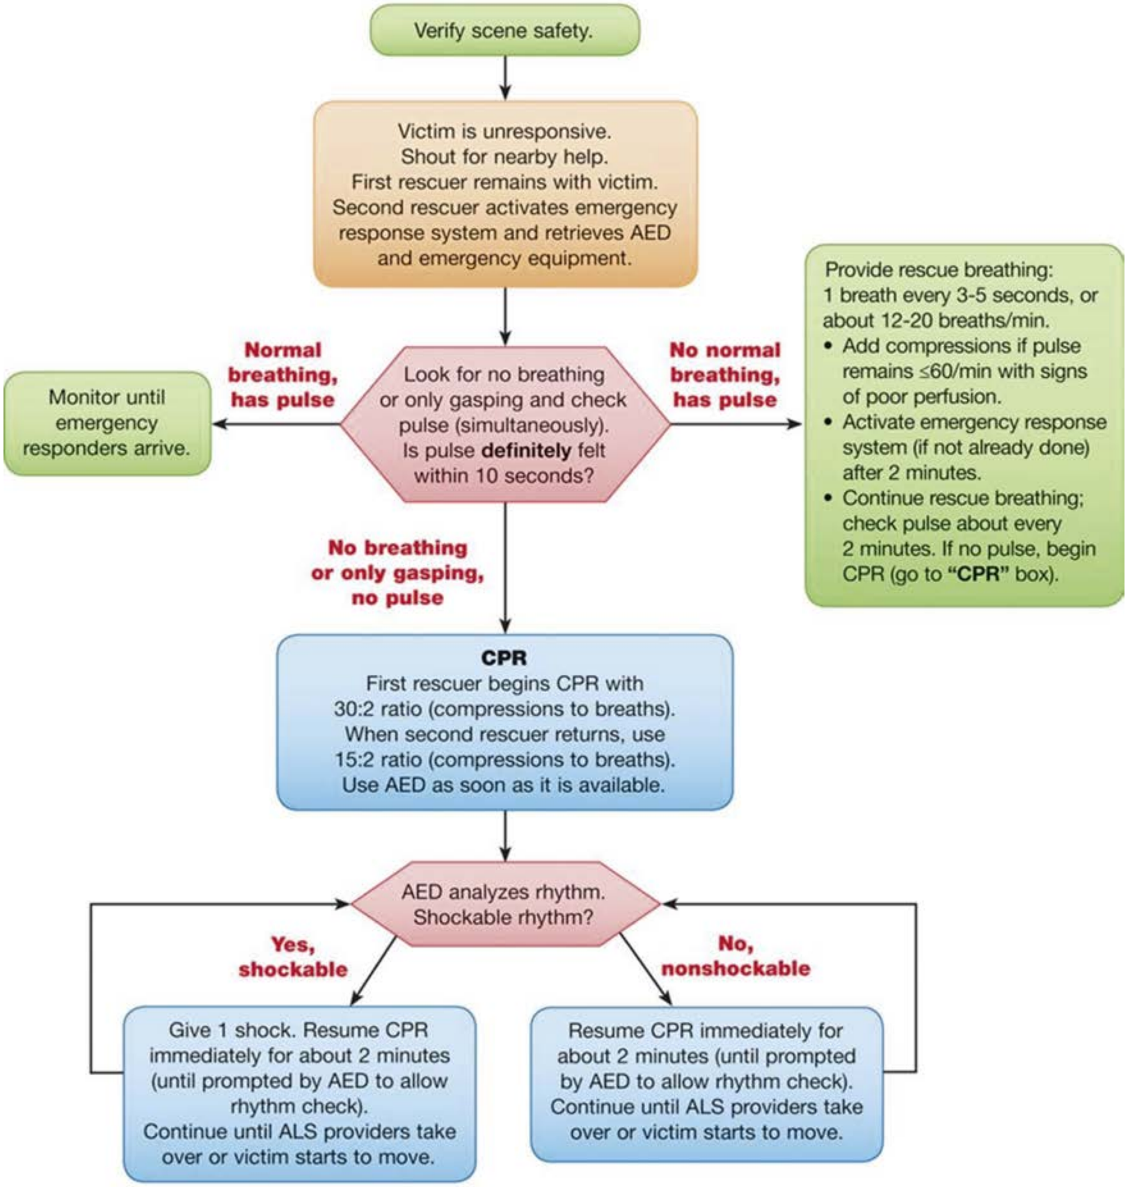
Fig. 86.9 2015 American Heart Association Pediatric Cardiac Arrest Algorithm for Single Rescuer. *AED*, Automated external defibrillator; *CPR*, cardiopulmonary resuscitation. (From Atkins DL, Berger S, Duff JP, et al. Part 11: Pediatric Basic Life Support and Cardiopulmonary Resuscitation Quality: 2015 American Heart Association Guidelines Update for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation*. 2015;132[18 suppl 2]:S519–525.)

The guidelines recommend the same chest compression rate as in adults: 100/min to 120/min. In infants, the rescuer should place two fingers just below the inframammary line on the sternum. In children, chest compressions should be performed by compressing the lower half of the sternum (avoiding the xiphoid process) with one or two hands. The guidelines also recommend that for pediatric patients (birth to the onset of puberty) the depth of chest compression should be at least one-third the anterior-posterior diameter of the chest. This equates to approximately 1.5 inches (4 cm) in infants to 2 inches (5 cm) in children. Once children have reached puberty, the recommended adult compression depth of at least 5 cm, but no more than 6 cm, is used for the adolescent of average adult size. Conventional CPR (chest compressions and rescue breaths) should be provided for pediatric cardiac arrests. The guidelines also recommended the use of feedback devices to help the rescuer optimize adequate



Verify scene safety.
Victim is unresponsive. Shout for nearby help. First rescuer remains with victim. Second rescuer activates emergency response system and retrieves AED and emergency equipment.
Normal breathing, has pulse
Monitor until emergency responders arrive.
Look for no breathing or only gasping and check pulse (simultaneously). Is pulse **definitely** felt within 10 seconds?
No normal breathing, has pulse
Provide rescue breathing: 1 breath every 3-5 seconds, or about 12-20 breaths/min.
• Add compressions if pulse remains ≤60/min with signs of poor perfusion.
• Activate emergency response system (if not already done) after 2 minutes.
• Continue rescue breathing; check pulse about every 2 minutes. If no pulse, begin CPR (go to "CPR" box).
No breathing or only gasping, no pulse
CPR
First rescuer begins CPR with 30:2 ratio (compressions to breaths). When second rescuer returns, use 15:2 ratio (compressions to breaths). Use AED as soon as it is available.
AED analyzes rhythm. Shockable rhythm?
Yes, shockable
No, nonshockable
Give 1 shock. Resume CPR immediately for about 2 minutes (until prompted by AED to allow rhythm check). Continue until ALS providers take over or victim starts to move.

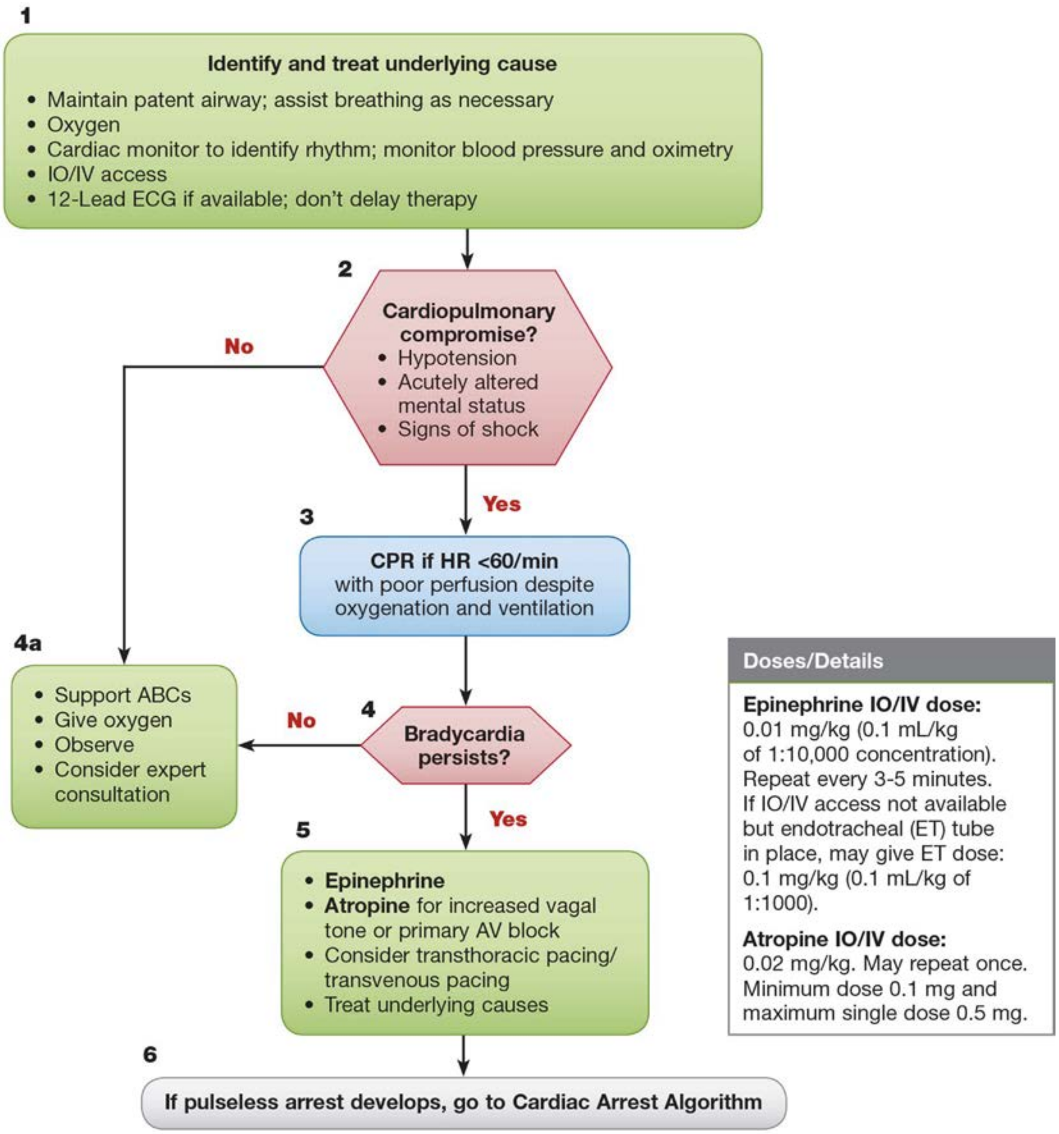
Fig. 86.10 2015 American Heart Association Pediatric Cardiac Arrest Algorithm for Two or More Rescuers. *AED*, Automated external defibrillator; *CPR*, cardiopulmonary resuscitation. (From Atkins DL, Berger S, Duff JP, et al. Part 11: Pediatric Basic Life Support and Cardiopulmonary Resuscitation Quality: 2015 American Heart Association Guidelines Update for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation*. 2015;132[18 suppl 2]:S519–S525.)

chest-compression rate and depth. End-tidal CO_2 ($ETCO_2$) monitoring may evaluate the quality of chest compressions, but specific values to guide therapy have not been established in children. For patients with invasive hemodynamic monitoring in place at the time of cardiac arrest, it may be reasonable for rescuers to use blood pressure to guide CPR quality.

The asphyxial nature of the majority of pediatric cardiac arrests necessitates ventilation as part of effective CPR. This survival benefit has been further supported by one recent large observational study where CPR using chest compressions with rescue breaths had higher survival to discharge rates than either no CPR or chest compression–only CPR.[90] However, because compression-only CPR is effective in patients with a primary cardiac event, if rescuers are unwilling or unable to deliver breaths, compression-only CPR is recommended for infants and children in cardiac arrest.

Sudden witnessed collapse in a child is likely to be from VF. For infants, a manual defibrillator is preferred when a shockable rhythm is identified by a trained healthcare provider. An AED with a pediatric attenuator and pediatric defibrillation pads is also preferred for children under 8 years of age. Pediatric defibrillator pads should be applied in the anteroposterior position. In pediatric cardiac arrest, initial defibrillation energy is 2 J/kg and increased to 4 J/kg if a second shock is indicated. For subsequent energy levels, a dose of 4 J/kg may be reasonable and higher energy levels may be considered, but should not exceed 10 J/kg or the adult maximum dose. If no pediatric defibrillator is available, then an adult AED should be applied and used without hesitation.



1
Identify and treat underlying cause
• Maintain patent airway; assist breathing as necessary
• Oxygen
• Cardiac monitor to identify rhythm; monitor blood pressure and oximetry

If pulseless arrest develops, go to Cardiac Arrest Algorithm
Doses/Details

Epinephrine IO/IV dose:
0.01 mg/kg (0.1 mL/kg of 1:10,000 concentration). Repeat every 3-5 minutes. If IO/IV access not available but endotracheal (ET) tube in place, may give ET dose: 0.1 mg/kg (0.1 mL/kg of 1:1000).

Atropine IO/IV dose:
0.02 mg/kg. May repeat once. Minimum dose 0.1 mg and maximum single dose 0.5 mg.

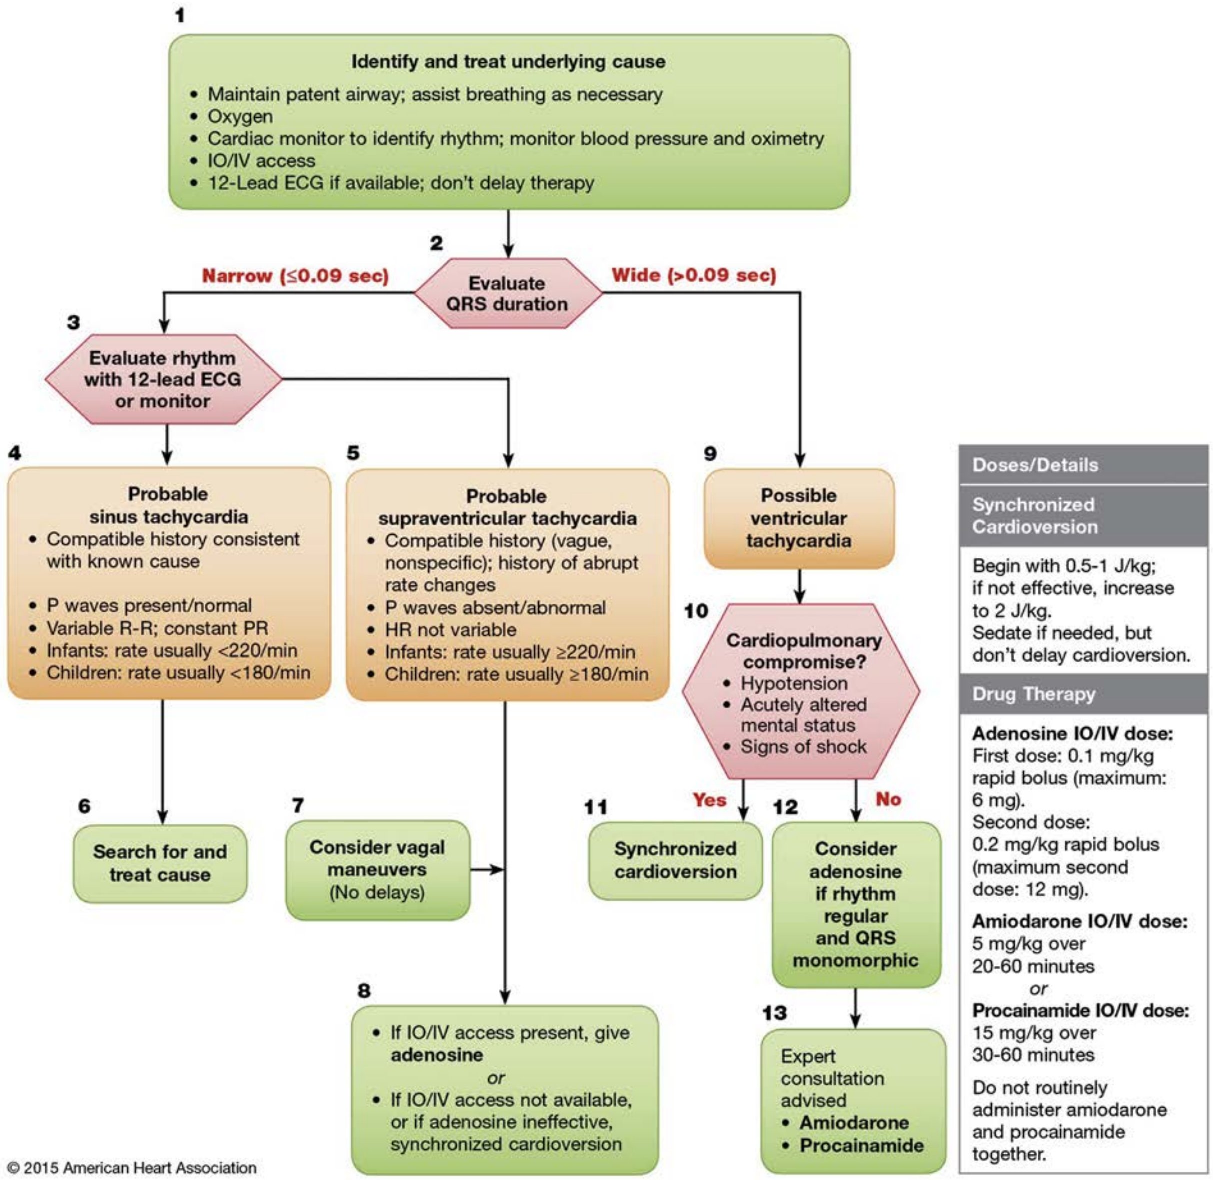
PEDIATRIC ADVANCED LIFE SUPPORT

Given the fact that asphyxiation is a much more common etiology of cardiac arrest in infants and children than primary cardiac events, effective basic and advanced airway management, oxygenation, and ventilation are of utmost importance. However, as with adult cardiac arrests, airway management should not cause prolonged interruption of chest compressions. Similarly, the placement of an advanced airway warrants confirmation of placement using a CO_2 detector and bilateral breath sounds. If the infant or child is intubated, ventilate at a rate of about 1 breath every 6 to 8 seconds (8-10 times/min) without interrupting chest compressions.

Because vascular access can be challenging in critically ill children and circulating medication levels between IV and intraosseous (IO) routes are equivalent, IO access is often pursued as an alternative in these patients. All resuscitation medications and blood products can be injected into IO catheters. Because of the resistance to fluid flow from the IO catheter into the IO space, fluids must be pressurized to carry fluid into circulation.

As in adults, ECG monitoring permits the immediate recognition of the arrest rhythm or the prearrest rhythm. Prompt intervention and correction in the latter event may prevent cardiac arrest of hypoxia etiology. For pediatric patients, management of different life-threatening arrhythmias, PEA arrest/asystole, or VF/VT arrest is similar to adults except the dosage (defibrillation/medication) for children is weight-based. Actual body weight is recommended to calculate initial resuscitation drug doses. The 2015 AHA Guidelines for CPR and ECC on pediatric ACLS for bradycardia, tachycardia, and pulseless arrest are illustrated in Figs. 86.11–86.13.[91]



1
Identify and treat underlying cause
• Maintain patent airway; assist breathing as necessary
• Oxygen
• Cardiac monitor to identify rhythm; monitor blood pressure and oximetry
• IO/IV access
• 12-Lead ECG if available; don't delay therapy
2
Evaluate QRS duration
Narrow (≤0.09 sec)
Wide (>0.09 sec)
3
Evaluate rhythm with 12-lead ECG or monitor
4
Probable sinus tachycardia
• Compatible history consistent with known cause
• P waves present/normal
• Variable R-R; constant PR
• Infants: rate usually <220/min
• Children: rate usually <180/min
5
Probable supraventricular tachycardia
• Compatible history (vague, nonspecific); history of abrupt rate changes
• P waves absent/abnormal
• HR not variable
• Infants: rate usually ≥220/min
• Children: rate usually ≥180/min
9
Possible ventricular tachycardia
10
Cardiopulmonary compromise?
• Hypotension
• Acutely altered mental status
• Signs of shock
Yes
No
6
Search for and treat cause
7
Consider vagal maneuvers (No delays)
11
Synchronized cardioversion
12
Consider adenosine if rhythm regular and QRS monomorphic
8
• If IO/IV access present, give adenosine
or
• If IO/IV access not available, or if adenosine ineffective, synchronized cardioversion
13
Expert consultation advised
• Amiodarone
• Procainamide
Doses/Details
Synchronized Cardioversion
Begin with 0.5-1 J/kg; if not effective, increase to 2 J/kg. Sedate if needed, but don't delay cardioversion.
Drug Therapy
Adenosine IO/IV dose:
First dose: 0.1 mg/kg rapid bolus (maximum: 6 mg).
Second dose: 0.2 mg/kg rapid bolus (maximum second dose: 12 mg).
Amiodarone IO/IV dose:
5 mg/kg over 20-60 minutes
or
Procainamide IO/IV dose:
15 mg/kg over 30-60 minutes
Do not routinely administer amiodarone and procainamide together.

For bradycardia, continue to support airway, ventilation, oxygenation, and chest compressions. Emergency TCP may be lifesaving if the bradycardia is due to complete heart block or sinus node dysfunction unresponsive to the aforementioned measurements and medications, especially if it is associated with congenital or acquired heart disease. For SVT, attempt vagal stimulation first, unless the patient is hemodynamically unstable or the procedure will delay chemical or electric cardioversion. An IV/IO dose of adenosine 0.1 mg/kg rapid bolus is used first; if it fails, then a second dose of 0.2 mg/kg rapid bolus is given, the maximum second dose is 12 mg. Verapamil, 0.1 to 0.3 mg/kg, is also effective in terminating SVT in older children, but it should not be used in infants without expert consultation because it may cause potential myocardial depression, hypotension, and cardiac arrest. When cardioversion is indicated in unstable SVT, start with a dose of 0.5 to 1 J/kg. If unsuccessful, increase the dose to 2 J/kg. For a patient with SVT unresponsive to vagal maneuvers and adenosine and/or electric cardioversion, consider amiodarone 5 mg/kg IO/IV or procainamide 15 mg/kg IO/IV; for hemodynamically stable patients, expert consultation is strongly recommended prior to administration. For wide-complex (>0.09 second) tachycardia, consider electric cardioversion after sedation using a starting energy dose of 0.5 to 1 J/kg. If that fails, increase the dose to 2 J/kg.

Regarding resuscitation medication, it is reasonable to administer epinephrine in pediatric cardiac arrest. For shock-refractory VF or persistent VT, either amiodarone or lidocaine may be used. Calcium administration is not recommended for pediatric cardiopulmonary arrest in the absence of documented hypocalcemia, calcium channel blocker overdose, hypermagnesemia, or hyperkalemia. Routine administration of sodium bicarbonate is not

CPR Quality

- Push hard (≥⅓ of anteroposterior diameter of chest) and fast (100-120/min) and allow complete chest recoil.
- Minimize interruptions in compressions.
- Avoid excessive ventilation.
- Rotate compressor every 2 minutes, or sooner if fatigued.
- If no advanced airway, 15:2 compression-ventilation ratio.

Shock Energy for Defibrillation

First shock 2 J/kg, second shock 4 J/kg, subsequent shocks ≥4 J/kg, maximum 10 J/kg or adult dose

Drug Therapy

- **Epinephrine IO/IV dose:** 0.01 mg/kg (0.1 mL/kg of 1:10,000 concentration). Repeat every 3-5 minutes.
  If no IO/IV access, may give endotracheal dose: 0.1 mg/kg (0.1 mL/kg of 1:1000 concentration).
- **Amiodarone IO/IV dose:** 5 mg/kg bolus during cardiac arrest. May repeat up to 2 times for refractory VF/pulseless VT.
- **Lidocaine IO/IV dose:** Initial: 1 mg/kg loading dose. Maintenance: 20-50 mcg/kg/min infusion (repeat bolus dose if infusion initiated >15 minutes after initial bolus therapy).

Advanced Airway

- Endotracheal intubation or supraglottic advanced airway
- Waveform capnography or capnometry to confirm and monitor ET tube placement
- Once advanced airway in place, give 1 breath every 6 seconds (10 breaths/min) with continuous chest compressions

Return of Spontaneous Circulation (ROSC)

- Pulse and blood pressure
- Spontaneous arterial pressure waves with intra-arterial monitoring

Reversible Causes

- **H**ypovolemia
- **H**ypoxia
- **H**ydrogen ion (acidosis)
- **H**ypoglycemia
- **H**ypo-/hyperkalemia
- **H**ypothermia
- **T**ension pneumothorax
- **T**amponade, cardiac
- **T**oxins
- **T**hrombosis, pulmonary
- **T**hrombosis, coronary

recommended in cardiac arrest. A dose of 0.02 mg/kg of atropine may be considered before emergency intubation.

Observational data from a registry of pediatric IHCA showed improved survival to hospital discharge with the use of ECMO cardiopulmonary resuscitation (ECPR) in patients with surgical cardiac diagnoses.[92] For children with underlying cardiac disease, when ECPR is initiated in a critical care setting, long-term survival has been reported even after more than 50 minutes of conventional CPR.[93] When ECPR is used during cardiac arrest, the outcome for children with underlying cardiac disease is better than for those with noncardiac disease.[94] Therefore, ECPR may be considered for pediatric patients with cardiac diagnoses who have IHCA in settings with existing extracorporeal membrane oxygenation (ECMO) protocols, expertise, and equipment.

For infants and children remaining comatose after OHCA, it is reasonable either to maintain 5 days of continuous normothermia (36°C-37.5°C) or to maintain 2 days of initial continuous hypothermia (32°C-34°C), followed by 3 days of continuous normothermia. Fever (temperature 38°C or higher) should be aggressively treated with antipyretics and cooling devices after ROSC.

Myocardial dysfunction and vascular instability are common after resuscitation from cardiac arrest.[95] After ROSC, IV fluids and/or inotropes or vasoactive drugs is recommended to maintain a systolic blood pressure greater than fifth percentile for age. When appropriate resources are available, continuous arterial pressure monitoring is recommended to identify and treat hypotension.

HIGHLIGHTING THE SIMILARITIES OR DIFFERENCES VERSUS ADULT RESUSCITATION

The similarities and differences of pediatric and adult BLS are listed in Table 86.1 and discussed in the Basic Life Support section. The asphyxial nature of the majority of pediatric cardiac arrests necessitates effective ventilation as part of the CPR. Conventional CPR (rescue breathing and chest compressions) should be provided for pediatric cardiac arrests. For infants, a manual defibrillator is preferred when a shockable rhythm is identified by a trained healthcare provider. An AED with a pediatric attenuator is also preferred for children less than 8 years of age. If neither is available, an AED without a dose attenuator may be used. As previously described, the defibrillation energy dose and resuscitation medication doses are all weight based.

FOREIGN BODY AIRWAY OBSTRUCTION

Although recognition and management has improved, foreign body aspiration (FBA) remains common in children. FBA can occur in children of all ages, although most occur in children younger than 4 years of age, with a peak incidence between the first and second years of age.[96] Liquids are the most common source for infant choking while small objects (e.g., balloons, food) are responsible for most childhood choking.[97] Clinical symptoms and signs vary based on the location of the foreign body and the degree of obstruction. The clinical presentation may also change over time as a result of movement of the foreign body within the respiratory tract.

If a child is making sounds or coughing, the adult should carefully monitor but not intervene. If the child is choking, abdominal thrusts (the Heimlich maneuver) or back blows should be performed until the obstruction is relieved. In either circumstance, if the choking infant or child becomes unresponsive, CPR should be started with 30 chest compressions, followed by an airway examination to identify the presence of the foreign body. Two rescue breaths should be attempted. If the airway obstruction is not relieved, then CPR should be restarted and continued until the airway obstruction is relieved. If a foreign body is visible above the vocal cords during laryngoscopy, an attempt should be made to extract it with Magill forceps. If the foreign body is below the vocal cords, it is reasonable to attempt to push the foreign body more distally to reestablish a patent airway. This may allow for rescue oxygenation and ventilation while preparing for more definitive management.

DROWNING

Drowning is an important cause of OHCA in children and results in approximately 1100 pediatric deaths in the United States annually.[98] It remains one of the leading causes of death in children and adolescents worldwide. The most important positive prognostic indicators include shorter submersion time, salt versus freshwater submersion, and time from rescue to receiving CPR.[99,100] Thus prehospital care is paramount to improve patient outcome.

When a drowning infant or child is encountered by a single rescuer, a CPR pattern of 2 minutes of 30:2 compression-to-ventilation should be provided before summoning help. If two or more rescuers are available, then help should be immediately summoned. Oxygen and ventilation should be provided at the earliest opportunity because respiratory arrest is usually the primary etiology. Heimlich maneuver is not beneficial in the case of drowned patients because it potentially increases time to intubation and the possibility of gastric aspiration.[101] Cuffed ETTs are preferred due to decreased lung compliance secondary to submersion-induced lung injury. The outcomes of survivors of cardiac arrest secondary to drowning are usually better compared with other respiratory etiologies.[102] However, it is very difficult to predict prognosis from initial presentation, with many of the most unexpected physiologic recoveries occurring in the young; therefore, aggressive resuscitation of a patient following submersion should always be undertaken until either ROSC or arrival at the emergency department, at which point further efforts such as ECMO may be considered.

SUDDEN UNEXPLAINED DEATHS

Unexpected and unexplained deaths in infants and children can result from cardiac and noncardiac etiology. Cardiac etiology is often attributed to cardiac arrhythmia caused by cardiac ion-channel dysfunction secondary to genetic variations or mutations, which may be undetectable in a conventional autopsy. In 2% to 10% of infants or children and 14% to 20% of young adults who experience sudden cardiac death, channelopathies are found on autopsy.[103,104] First- and second-degree relatives of young children who unexpectedly die should undergo a genetic analysis to detect undiagnosed channelopathies. Noncardiac conditions include epilepsy, upper airway obstruction from infectious/noninfectious reasons resulting in respiratory arrest, febrile seizures, infection, metabolic disorders, and hippocampal pathology.[105]

TERMINATION OF PEDIATRIC RESUSCITATION ATTEMPTS

Accurate and reliable prognostication during pediatric cardiac arrest would allow termination of CPR when it is futile, while encouraging continued CPR in patients with a potential for good recovery. Several post-ROSC factors have been studied as possible predictors of survival and neurologic outcome after pediatric cardiac arrest. These include the presence of hypotension, serum neurologic biomarkers, and serum lactate. Although these factors are associated with better or worse outcomes, no single factor predicts outcome with sufficient accuracy to recommend termination or continuation of CPR. The AHA 2015 Guidelines for CPR and ECC on pediatric ACLS recommend that multiple variables are used when attempting to prognosticate outcomes during cardiac arrest.

Observational data from two small pediatric studies showed that a continuous and reactive tracing on an EEG performed in the first 7 days after cardiac arrest is associated with a significantly higher likelihood of good neurologic outcome at hospital discharge. In contrast, an EEG demonstrating a discontinuous or isoelectric tracing is associated with a poor neurologic outcome at hospital discharge.[106,107] Thus EEG within the first 7 days after pediatric cardiac arrest may be considered in prognosticating neurologic outcome at the time of hospital discharge, although it should obviously never be used as the sole criterion.

Prolonged resuscitations might be considered for infants and children with recurring or refractory VF or VT, particularly if cardiopulmonary support with ECMO is available and the source for the cardiac arrest is believed reversible.[108]

Future of Resuscitation Science and Care

INDIVIDUALIZED CARDIOPULMONARY RESUSCITATION

As described earlier in this chapter, survival and neurologic outcome in victims of cardiac arrest are critically dependent on the duration of the "no-flow" arrest (circulatory arrest with no chest compressions), as well as the quality of chest compressions during the "low-flow" phase of CPR. Therefore, it is important to provide early and high-quality chest compressions and to use every measure to facilitate early ROSC, irrespective of the cause of the arrest. Recent data have, nevertheless, shown that in addition to this general approach, interventions aimed at specific conditions or physiologic parameters can also affect the chance of ROSC and survival. This individualized approach to CPR has become increasingly important given the persistent poor outcome after cardiac arrest despite efforts to improve implementation of current guidelines, AED accessibility, and provider training.

The use of ECG filtering techniques and fibrillation analysis algorithms has been investigated to identify the optimal time for successful defibrillation from VF. A problem coherent to this technique has been the need to stop chest compressions for rhythm analysis, which is proven to adversely affect the effectiveness of the subsequent chest compressions. The recent development of the "See-Through" technology to extract CPR artifacts from the ECG is promising, as it allows continued chest compressions during ECG analysis but has been criticized for a relatively low specificity that prohibits its incorporation into the AED diagnostic algorithm.[109] Amplitude spectral area (AMSA) is an index for analyzing ventricular fibrillation waveforms to predict ROSC after defibrillation. Nakagawa and associates showed that change in AMSA (ΔAMSA) before the electric shock reliably predicted ROSC in 285 VF patients.[110] Segal and associates report a moderate positive correlation between $ETCO_2$ and AMSA during CPR in pigs.[111]

As was described in the 2015 AHA Guidelines for CPR and ECC ACLS update, provider performance feedback during CPR can also help optimize CPR quality. Despite the absence of convincing evidence, it is reasonable to use quantitative waveform capnography, arterial pressure monitoring, and central venous oxygen saturation when feasible to monitor and optimize CPR quality and guide vasopressor therapy. Gonzalez-Otero and associates recently reported that an accelerometer-based real-time feedback system to guide rescuers during CPR can improve adherence to published resuscitation guidelines. Spectral analysis of chest acceleration was used to compute the depth and rate of chest compressions.[112] The use of a novel CPR card feedback device was also shown to improve the quality of chest compressions.[113]

In addition to interventions aimed at improving the quality of chest compressions, recent data suggest that optimization of oxygen delivery to the ischemic tissue can also be complemented by enhanced ventilation strategies. Chest Compression Synchronized Ventilation (CCSV) is designed to detect starting chest compression efforts and to initiate an instant inspiratory pressure through reprogramming of the Pressure Support Ventilation mode. It comprises an inverse trigger, cycling mechanisms, and higher inspiratory pressure levels up to 60 mbar. Kill and colleagues showed that when compared with Intermitted Positive Pressure Ventilation (IPPV), CCSV results in a higher PaO_2 without an arterial blood pressure drop during resuscitation in pigs.[114] The same group of investigators reported that CCSV is associated with better delivery of the respiratory parameters and minimizes excessive inspiratory pressures that can potentially lead to pulmonary injury during simulated CPR.[115]

Extracorporeal Membrane Oxygenation

ECMO with CPR (ECPR) continues to evolve as a therapeutic option for refractory cardiac arrest.[116] Its use has significantly increased over the last few years, and new techniques are being developed to enhance its feasibility and access.[117] In a meta-analysis of 10 recent publications, Kim and associates reported a trend toward improved short-term (3-6 months) survival and neurologic outcome with ECPR as compared with conventional CPR.[118] Debaty and associates reported that shorter low-flow duration, shockable cardiac rhythm, higher arterial pH value, and lower serum lactate concentration on hospital admission are associated with better outcomes for ECPR recipients after OHCA.[119] Dennis and associates confirmed that in selected patients with refractory cardiac arrest, ECPR may provide temporary support as a bridge to intervention or recovery. Favorable survival and neurologic outcomes were reported in one-third of patients with pre-ECMO lactate levels predictive of mortality.[120]

Controlled Automated Reperfusion of the whole body (CARL) is a new type of extracorporeal circulation device that provides continuous adjustments of reperfusion conditions with the recirculating blood according to the individual readings of each patient. It combines measures to control arterial blood pressure and blood flow with TTM, as well as control of the acid-base status, oxygen content, osmolarity, and electrolytes to minimize the ischemia-reperfusion injuries. Based on data from experimental studies, recently Trummer and associates successfully employed CARL after 120 minutes of normothermic CPR in a patient. Except for a spinal cord injury resulting in lower extremity weakness, the patient was reported to have survived without any neurologic deficits.[121]

Emergency preservation for delayed resuscitation (EPR) or suspended animation is another promising approach to enable intact survival in patients who are expected to fail conventional resuscitation techniques. It was developed by the Safar team at the University of Pittsburgh to apply profound hypothermia to preserve the organism and avoid irreversible organ damage and buy enough time to obtain surgical hemostasis in victims of exsanguination cardiac arrest. This concept has been tested successfully in multiple large animal studies, confirming that full recovery is possible for up to 2 hours of no-flow cardiac arrest when profound hypothermia to 10°C is induced within minutes, and is then followed by delayed resuscitation using cardiopulmonary bypass or extracorporeal circulation. Tisherman and associates recently reported the development of the first multicenter clinical trial of EPR in victims of traumatic cardiac arrest.[122] If successful, EPR can also be employed as an alternative resuscitation approach in patients with refractory intraoperative exsanguination cardiac arrest.

COORDINATED POSTRESUSCITATION CARE

Postresuscitation syndrome is a complex pathophysiologic condition first described by Negovski and associates in the 1970s, and can significantly affect the outcome after cardiac arrest.[123] It is characterized by myocardial dysfunction, neurologic injury, and systemic perturbations associated with the reperfusion of the ischemic tissue. Post–cardiac arrest care must therefore incorporate measures to minimize the systemic ischemic-reperfusion response, improve myocardial function, and prevent postresuscitation brain injury and other systemic complications. It is recommended that survivors of cardiac arrest are admitted to specialized centers for early goal-directed therapy, including optimization of the hemodynamics and respiratory parameters, urgent coronary angiography, and TTM. It is important to note that TTM is considered in all comatose survivors of cardiac arrest, whose temperature should be monitored closely (goal between 32°C and 36°C) for at least 24 hours. It is also recommended to continue monitoring the temperature and maintain normothermia (treat fever) beyond this window. Prognostication should not occur until 72 hours after ROSC or, if TTM is provided, 72 hours after completion of TTM. A useful tool to predict outcome after cardiac arrest is the GO-FAR score, which was derived from the Get With the Guidelines-Resuscitation registry and identifies a large proportion of patients (28.3%) who have a low or very low likelihood (<2%) of achieving good outcome.[124] Seizure control is also important, but neuroprotective agents such as thiopental, magnesium, and calcium channel inhibitors are not routinely administered and have not been shown to improve outcomes. With the evolution of ECPR, nevertheless, there has been a resurgence of studies aimed at identifying effective neuroprotective agents. Examples include adenosine 2A receptor (A2AR) agonists, which have been suggested to attenuate the ischemia-reperfusion injury during ECPR.[125] A2AR activation can reduce proinflammatory mediators, endothelial adhesion molecule expression, and transmigration of circulating inflammatory cells into tissue through inhibition of lymphocytes, macrophages, monocytes, platelets, and neutrophils. Inhaled nitric oxide (iNO) is also an emerging approach to the treatment of the post–cardiac arrest syndrome and to reducing the ischemia-reperfusion injury. In a pig model of cardiac arrest precipitated by lipopolysaccharide–induced hypotension, Morgan and associates showed that pulmonary vasodilation with iNO improved short-term survival and intra-arrest hemodynamics.[126] Human studies are forthcoming, but there are currently insufficient data to recommend routine use of any of these novel therapies.

Acute and Anesthetic Care of the Burn-Injured Patient

EDWARD A. BITTNER, J.A. JEEVENDRA MARTYN, and FOLKE SJÖBERG

KEY POINTS

- Major burn injury results in pathophysiologic changes affecting virtually all organs from the onset of injury until wounds are healed. Anesthesiologists are often called on to care for burn injury patients through their hospitalization including acute airway management and resuscitation, intraoperative anesthetic care, intensive care, and management of postoperative pain.
- Burn shock is a paradigm of ischemia/reperfusion injury. The initial ischemic (ebb) phase of burn shock is a hypodynamic, hypovolemic state, with rapid loss of fluid from the intravascular space and decreased cardiac output, which typically lasts for the first 24 to 48 hours following injury. Approximately 48 hours after successful resuscitation, a hyperdynamic, hypermetabolic (flow) phase ensues consisting of tachycardia, increased cardiac output, hyperthermia, hyperglycemia, and increased protein catabolism.
- The goal of fluid resuscitation is to maintain organ perfusion by replenishing the massive loss of fluid from intravascular to extravascular compartments. Multiple fluid resuscitation formulae exist for estimating fluid needs and differ somewhat in their recommendations for the amount of crystalloid and colloid replacement. No matter which formula is used, it should serve only as a guideline, and fluid resuscitation should be titrated to physiologic endpoints.
- Inhalation injury is a major prognostic factor for morbidity and mortality after burn injury. Management of inhalation includes observation and monitoring. Endotracheal intubation or tracheostomy is indicated if airway patency is threatened.
- Patients with severe burn injury often suffer from nonthermal traumatic injuries. Failure to diagnose these associated injuries during initial evaluation can lead to serious morbidity and mortality. All burn patients should be approached initially as multiple-trauma patients.
- The magnitude of burns is classified according to percentage of total body surface area (TBSA) involved, depth of the burn, and the presence or absence of inhalational injury. Accurate estimation of burn magnitude is needed to guide the initial resuscitation strategy, make the referral to a burn center, ascertain the need for surgery, and to estimate prognosis. Three of the most commonly used methods to estimate %TBSA are the "rule of nines," palmar surface area, and the Lund-Browder diagram.
- "Fluid creep" refers to the trend of over-resuscitation in burn injury patients. Overly aggressive fluid administration may result in pulmonary edema, compartment syndromes, multiorgan failure, nosocomial infection, and increased mortality as well as the extension of the burn injury because of excessive local edema. Factors that contribute to "fluid creep" include overestimation of the burn size, use of supra-physiologic hemodynamic targets, increased opioid utilization, and failure to reduce the rate of fluid administration in patients with evidence of adequate tissue perfusion.
- Electrical burns can have acute and chronic effects not occurring with other types of burn injury, and with morbidity far higher than expected based on burn size estimation alone. High-voltage injuries are typically associated with loss of consciousness, arrhythmias, myoglobinuria, and extensive deep tissue damage that can result in compartment syndromes. Patients suffering from electrical injury should be evaluated for associated traumatic injury, rhabdomyolysis, and compartment syndromes. For treatment of these complications, patients may come to the operating room within 24 hours of injury.
- Airway management in the burn-injury patient may be challenging and warrants particular consideration. Key features of airway assessment include preexisting airway abnormality, current airway injury (i.e., inhalation injury), and signs of glottic obstruction. The type of airway abnormalities may vary depending on the stage of the injury. In the acute burn setting, mandibular mobility and mouth opening may be limited because of edema or, in later care, may have significant scarring and contractures in the face, mouth, nares, neck, and chest which can make airway management difficult.
- Burn-injured patients develop tolerance to most narcotics and sedatives, thereby requiring substantially higher doses than patients without thermal injury. Sedatives and narcotics should be titrated to effect while the patient is carefully monitored. Adverse effects of opioids, such as respiratory depression, acute opioid tolerance, and hyperalgesia, particularly with the need for rapidly escalating doses, have generated increasing attention to multimodal strategies.

- Muscle relaxant pharmacology is significantly and consistently altered after burn injury. Exposure to succinylcholine can result in an exaggerated hyperkalemic response, which can induce cardiac arrest. The current recommendation is to avoid succinylcholine administration in patients 48 to 72 hours after burn injury. The duration of this dangerous response to succinylcholine after burn injury is unknown.
- Surgical excision of burn wounds is often associated with substantial bleeding. It is not uncommon for the surgical team to remove eschar so rapidly that the patient becomes hypovolemic and hypotensive. Clinical judgment remains a vital component for intraoperative resuscitation, using markers of perfusion, erythrocyte mass, and coagulation, pulse, or arterial waveform as key assessment tools. Good communication between the surgical and anesthesia teams as well as limiting the operative duration and extent of excision are also essential.
- Patients with major burn injury have an impaired ability for thermoregulation and therefore require close monitoring of body temperature. Multiple strategies are used to maintain body temperature in the operating room, including use of forced-air warming blankets, thermal water mattresses, blood/fluid warmers, minimizing skin surface exposure, and wrapping the head and extremities with plastic or thermal insulation.
- Postoperatively, burn-injured patients are likely to be less stable physiologically compared with the preoperative period. Continued bleeding may be concealed by dressings, the patient may be more prone to hypothermia, emergence may be associated with delirium, and analgesic requirements will be greater. During this period of exaggerated physiologic fragility, it is important to be especially vigilant during transfer of the monitors and respiratory and hemodynamic support equipment to the intensive care unit staff.
- Burn injury leads to increased susceptibility to infection due to decreased immunity through multiple mechanisms including loss of the physical barrier of intact skin, damage to lining of the respiratory tract from inhalation injury, and altered gut permeability and function. Preventative measures against infection are critical for the burn-injury patient and include early excision of burn eschar to improve local perfusion and prevent microbial colonization, prudent use of invasive devices, application of antimicrobial burn dressings, and diligent compliance with infection control.
- Nearly all aspects of burn care (e.g., dressing changes, excision and grafting procedures, physical therapy, and line insertion) are associated with pain. There can be ongoing background pain, periodic breakthrough pain, procedure-related pain, and eventually, chronic pain can develop. Standardized pain and anxiety guidelines are used to provide appropriate, consistent patient comfort.

Introduction

Burn injuries are among the leading causes of injury and death worldwide, with about 11 million seeking medical care and over 265,000 deaths annually. Over 95% of these occur in low- and middle-income countries.[1] Approximately 486,000 burn injuries are treated at U.S. medical facilities each year of which 40,000 require hospital admission with approximately 3275 deaths.[2]

Major burn injury produces pathophysiologic changes that affect virtually all organs from the very onset of injury until after the wounds heal. Pathophysiologic effects may persist for years especially in patients with major injuries and include insulin resistance, neuromuscular dysfunction, pruritus, pain, and more frequent hospital admissions related to infections and cardiomyopathies.[3-5] Severe burn injury patients are different from other intensive care patients as they pose challenges regarding fluid resuscitation, metabolic stress, perioperative demands, and other specific burn injury–related complications. Most burn injury patients present to emergency rooms in community hospitals, which do not have a designated burn center. After initial acute care, these patients are usually transferred to tertiary care facilities with a specialized burn center. As a result, anesthesiologists staffing these peripheral hospitals with emergency rooms must be familiar with the pathophysiology of acute burn injury and resuscitation. In addition, treatment of a burn injury patient requires multiple operations, frequent dressing changes, and prolonged hospital stay with extensive rehabilitation needs. In burn care facilities, anesthesiologists need to have expertise in the specific management of the pathophysiologic changes affecting these victims and particularly the unique features of perioperative management of this patient population. Therefore there is a continuous need for specific teaching, training, and maintenance of specialized skills in this field.[6]

Although morbidity from burn-related injuries remains high, advanced methods of resuscitation, early excision and grafting of burn wounds, better methods of wound coverage, improved anesthesia and intensive care techniques, early diagnosis and aggressive treatment of infections, as well as enhanced nutritional support and mental health–care methods have led to significant decrease in burn injury–related morbidity and mortality. Other factors, including immediate prehospital care, early emergency treatment with advanced life support capability, and secondary transfer to a specialized burn unit have also contributed to improved survival.[7] Despite significant advances in therapeutic strategies, care of the burn injury patient continues to pose multiple challenges for clinicians.

Pathophysiology

BURN SHOCK

Burn injury can cause massive tissue destruction and result in activation of an inflammatory response that leads to profound pathophysiologic effects at sites both local and distant from the injury. Understanding the pathophysiologic alterations and their time course is essential for providing appropriate resuscitation and perioperative care.

Burn shock is a paradigm of ischemia/reperfusion injury.[8] The initial ischemic (ebb) phase of burn shock is a hypodynamic, hypovolemic state, with rapid loss of fluid from the intravascular space and decreased cardiac output, which typically lasts for the first 24 to 48 hours following injury. A large volume fluid resuscitation is required to maintain intravascular volume for organ reperfusion, acutely diluting plasma proteins. Approximately 48 hours after successful resuscitation, a hyperdynamic, hypermetabolic (flow) phase ensues due to the systemic inflammatory responses from the trauma-induced release of damage-associated molecular patterns (DAMPS), even in the absence of overt infection.[9] This is characterized by increased cardiac output, oxygen consumption, muscle protein catabolism, and body temperature, lasting for many months to years after healing of the burn wounds. When burn shock is left untreated, physiologic exhaustion ensues and is fatal.

The goal of fluid resuscitation is to maintain organ perfusion by replenishing the massive loss of fluid from intravascular to extravascular compartments. There are two main reasons for this loss, both of which have been extensively investigated and have clear temporal patterns. First, there is the negative imbibition pressure in tissues injured by a burn[10-13] and, second, there is an increase in vascular permeability with loss of fluid from the vasculature as well as from the injured areas.[14] In the injured areas, there is protein loss from the vasculature in addition to crystalloid loss. At the uninjured distant sites, there is capillary sieving of protein with loss of crystalloid only.[15]

NEGATIVE IMBIBITION PRESSURE

When fluid losses were investigated in experimental models they could not be explained completely by an increase of permeability, and it was then postulated that there must be another mechanism that would explain these losses. In 1960, Gösta Arturson suggested that the loss from the blood could be explained by a reduction in the interstitial tissue pressure.[16] Subsequently, Lund et al. using in vitro models showed that there is a build-up of strong negative interstitial pressure within injured tissue causing a negative interstitial pressure in the range of −25 to −50 mm Hg (Fig. 87.1).[17] This negative gradient, called negative imbibition pressure, explains most of the early total fluid loss. Imbibition pressure is a negative pressure where water or crystalloid is absorbed causing large increases in volume and is different from hydrostatic and osmotic pressure. More recent in vivo studies by Kinsky and associates have confirmed the previous in vitro findings on imbibition pressure.[18] This negative imbibition pressure is most pronounced immediately after the burn and remains for several hours. Intriguingly, the fluids provided during resuscitation seem to have an adverse effect on the negative imbibition pressure (see Fig. 87.1). Administering a greater amount of fluid results in larger negative tissue imbibition pressure, and correspondingly larger fluid leak and overall demand for fluids. The mechanism underlying the development of negative tissue pressure is not well understood, but probably results from the effect of thermal energy on the tissue integrins (components important for the regulation of hydrostatic pressure in the interstitium), which lose the ability to maintain their beneficial effect on imbibition pressure. The magnitude of the burn seems to affect this defect; the larger the burn injury, the more pronounced is the negative pressure in the tissue.[13] This is the reason for early hypovolemia despite fluid treatment therapy. Importantly, most of the intravascular fluid loss disappears within 24 to 48 hours.[20] The resorption of the extravascular edema fluid, however, takes much longer as detailed later in the *Fluid Resuscitation Strategies* section.

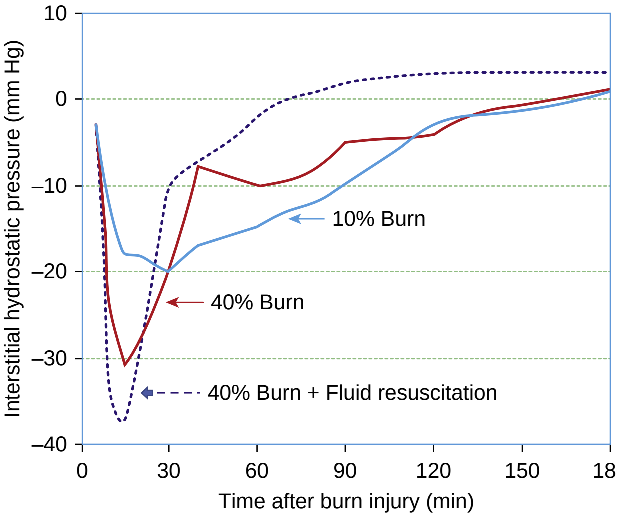

Fig. 87.1 Negative imbibition pressure. Graph showing how negative interstitial fluid pressure changes over time and varies based on the size of the burn injury and the administration of fluid.

PERMEABILITY EFFECTS OF THE BURN

The loss of fluid from the intravascular space is also due to the increase in vascular permeability. This effect is obvious even in a small 5% total body surface area (TBSA) burn and occurs soon after the injury, explaining the blister formation even with small burn injury. Detailed mechanisms as to how even a small burn causes leakage of fluid is unclear, but there seem to be a number of putative mediators (see also section on Mediators Important in Fluid Loss). Another important aspect of vascular permeability is the onset of vasodilatation in most vascular beds as a result of the continued liberation of proinflammatory cytokines into the injured tissues. This vasodilatation increases the hydrostatic pressure in the microcirculation, which leads to further loss of fluid into the interstitial compartment. The Starling equation given here further describes the different factors that play a role in fluid filtration:[20]

$$J_{\mathrm{V}} = \mathrm{Kf}\left(\left(P_{\mathrm{c}} - P_{\mathrm{i}}\right) - \sigma\left(\pi_{\mathrm{c}} - \pi_{\mathrm{i}}\right)\right)$$

where J_{V} is the fluid volume, Kf the filtration coefficient, P_{c} the capillary hydrostatic pressure, P_{i} the interstitial hydrostatic pressure, σ the reflection coefficient, π_{c} is the capillary osmotic pressure, and π_i the interstitial osmotic pressure. In particular, the coefficient of filtration increases dramatically, often to a range 20-fold greater; for the latter parts of the formula, there is an increase in hydrostatic pressure in the capillaries due to vasodilatation; decrease in interstitial pressure (the negative imbibition pressure) together with a decrease in colloid osmotic pressure within the capillaries as the result of a capillary leak, onto which also the increased osmotic effect of proteins lost into the interstitium, is added.

Although these changes affect most vascular compartments, the effect at the venular-end seems more important from a quantitative perspective. Most of the proteins lost across the vascular wall are smaller molecules; a few larger proteins are also lost. This large protein loss is important to note, as it underlies the arguments in favor of so-called "colloid rescue" fluid resuscitation in larger burns, which reduces the total colloid loss (and corresponding total fluid loss) with decreased risk of compartment syndromes.[22] It is important to stress that the loss of fluid from the intravascular space is due to alterations in ***all*** the factors previously described, which are important for the transport of fluid across the capillary and venular walls, and therefore contribute to the large fluid volume loss after burn injury.

In clinical practice, the increase in permeability, dilution effects of the resuscitation, and loss of protein manifest as a decrease in the concentration of serum albumin. The intravascular colloid osmotic pressure during the acute phase of burn injury is dependent not only on albumin but also on the newly synthesized acute phase proteins. Uncertainties in the temporal pattern of the vascular leak of protein locally means that the optimal timing of colloid administration is unclear. Thus the intense debate as to when colloids can safely be started during fluid resuscitation continues. Today most burn clinicians would agree that it is appropriate to start colloids 8 to 12 hours postburn to reduce the total fluid volume (see section *Colloid Rescue Treatment*). It is important to understand, however, that early colloid administration may lead to its extravasation into the extravascular space with a concomitant increase in tissue edema. It must also be noted that even in the absence of burn injury only 20% of the administered crystalloid fluid volume stays within the vasculature, and that large volumes of crystalloid alone will decrease intravascular colloid osmotic pressure and cause a further loss of fluid from this compartment.[23] These interrelated effects must be appreciated when fluid resuscitation for a burn injury patient is initiated. However, the previous dictum that the first 24 hours after burn should consist of only crystalloids does not hold anymore.

FLUID LOSS IN BURNS: THE TEMPORAL ASPECT

When caring for burn injury patients, it is important to discuss the temporal aspects of the fluid loss, and the recommended fluid management. This is particularly important, as recent investigations have shown that in present guidelines there is a clear temporal mismatch between fluid loss and fluid volume protocols. Most of the fluid that is lost from negative imbibition pressure is lost within the first 3 to 4 hours after the burn. The picture is somewhat different for the fluid that is lost from the increase in permeability. The most reliable data in humans has suggested that this fluid is lost at the time of the injury, and up to 8 to 10 hours later.[24,25] The permeability effects continue even after 48 hours due to the continuous systemic inflammatory response that is ongoing after the burn, although its magnitude is significantly less, unless complicated by sepsis.

More important is that the present guidelines for fluid resuscitation, particularly if they are based purely on crystalloids, do not fully account for this early loss of fluid. The patient may therefore be claimed to be in a controlled hypovolemic state during the first 12 to 16 hours after the burn injury. The tissue edema reaches its maximum between the first 24 to 48 hours after the injury, and thereafter the added fluid volume is slowly returned to the circulation and excreted as urine, often until 7 to 14 days after the burn depending on the magnitude of the injury.[26] This is also the time when lung dysfunction can occur because of hypervolemia from the reabsorbed fluid.

Mediators Important in Fluid Loss

Many mediators have been thought to be important in the underlying mechanisms of fluid loss in burns, and there are probably several that contribute in different ways. The most important are: serotonin, nitric oxide, thromboxanes, prostaglandins, and several others including reactive oxygen species and proinflammatory cytokines.[27] But molecular mediators are not the only substances implicated in the permeability effects; white blood cell–related effects have also been suggested.[28,29] Coagulation and the complement cascade are thought to be activated early, and also play an important part. Interest in the mediators and their possible role in the generation of fluid losses is driven by the hope of finding a treatment that can stop or reduce the process. Some attempts have been made and the most successful has been the use of high-dose vitamin C (as a scavenger of oxygen radicals) which, in randomized trials in both animals and humans, showed a reduction in fluid loss in the treatment arm.[30,31] In addition, direct effects were seen on the negative imbibition pressure with vitamin C administration.[32]

Hemodynamic Alterations

Burn shock can result in profound hemodynamic alterations associated with organ dysfunction. Severe burn shock is both distributive and hypovolemic in nature. The increased systemic vascular resistance (SVR) (due to release of catecholamines, antidiuretic hormone, and hemoconcentration) compounds the shock phase adverse effects.

A reduction in cardiac output also often occurs with major thermal injury even before any detectable reduction in plasma volume and may continue even when hypovolemia is alleviated.[33] The cardiac dysfunction is characterized by slowed isovolemic relaxation, impaired contractility, and decreased left ventricular diastolic compliance and often continues for 24 to 36 hours.[34,35] Burn-related left ventricular contraction and relaxation defects increase with burn size, achieving a nadir with 40% TBSA burns.[36] This cardiac dysfunction has been identified as a major cause of multiple organ dysfunction syndrome (MODS) and mortality.

A hyperkinetic and hypermetabolic state develops 48 to 72 hours after burn injury, and is characterized by a decrease in vascular permeability, increased heart rate, and decreased SVR resulting in an increase in cardiac output.

Cardiac output is often increased to more than 1.5 times that of a nonburned, healthy patient 3 to 4 days following the injury. The metabolic rate is increased, approximately 1.5 times that of normal basal rate.[37] This increase in cardiac output is associated with increased liver and kidney blood flow, which has implications for elimination of blood flow–dependent drugs including some antibiotics and anesthetic drugs. The onset of sepsis may further increase cardiac output and decrease SVR.

Inhalation Injury

PATHOPHYSIOLOGY

In addition to age and the extent of burns, inhalation injury is a major prognostic factor for morbidity and mortality after burn injury. Inhalation injury can be classified under three subcategories: direct thermal injury to the upper airway; chemical irritation to the lower (subglottic) airway and even lung alveoli; and systemic chemical or metabolic injury caused by specific noxious combustion chemicals, or a combination of these factors.[38] Direct heat and steam injury to the upper airway can lead to marked swelling of the face, tongue, epiglottis, and the glottic opening resulting in an upper airway obstruction. Because airway swelling may not occur immediately but may develop over a period of hours (especially with, and complicated by, concurrent fluid resuscitation), a high index of suspicion and frequent reevaluations of the respiratory status are essential. A scald injury of the epiglottis may mimic symptoms of epiglottitis.[39]

Thermal injury to the lower airway is uncommon due to a highly efficient heat exchange system in the oropharynx and nasopharynx and the low specific heat of steam in conjunction with the laryngeal closure reflex due to the irritation. Damage to the lower airways and lung parenchyma following smoke inhalation tends to be chemical rather than thermal. Toxic substances in smoke damage the epithelium and capillary endothelial cells of the airway resulting in the release of inflammatory mediators, increased vascular permeability, and edema of distal bronchi and alveoli. Many of the previously listed mediators are relevant here as well. Damaged mucosal cells produce excess exudates rich in protein and necrotic debris. Chemicals in smoke promote the formation of neutrophil-generated oxygen radicals leading to inflammation. Destruction and damage to the airway's ciliary transport function leads to the accumulation of casts, airway plugging, and impaired clearance of bacteria and debris.[40] Alveolar collapse and atelectasis can occur because of loss of surfactant production or from plugging of small airways by mucosal debris. Over time, these changes can result in bronchospasm, airway obstruction, atelectasis, and pneumonia, which cause ventilation perfusion mismatch, impaired gas exchange, and decreased pulmonary compliance. The severity of inhalation injury may not be directly proportional to the degree of exposure to smoke alone. Rather, the severity of injury is probably due to the composition of the inhaled material and combustion substances together with differences in the individual host response as well as added effects from the cutaneous burn.

Injury to the airways and lung can also occur with severe cutaneous burns in the absence of inhalational injury. Mechanisms include the effects of inflammatory mediators from the burn-injured area, and the effects of fluid resuscitation and infection. For example, acute lung injury can occur in patients with scald injury without smoke exposure where bronchoscopic features can mimic smoke-induced airway injury.[41,42]

While the gas-phase components of smoke do not produce direct injury to the respiratory tract, they can produce systemic effects. Among the most toxic gas-phase components are carbon monoxide (CO) and cyanide inhalation, which can lead to major morbidity and mortality following inhalation injury. CO is an odorless, colorless gas that has a 200-fold higher affinity than oxygen to the same binding sites on hemoglobin.[43] CO shifts the oxyhemoglobin dissociation curve to the left and alters its shape. In addition, CO binds to cytochrome oxidase, impairing mitochondrial function and reducing adenosine triphosphate (ATP) production. CO thus reduces both the oxygen-carrying capacity of blood and oxygen dissociation at a tissue level, as well as disrupting oxidative cellular respiration. The clinical manifestations with patient symptoms of CO poisoning appear when carboxyhemoglobin (HbCO) levels are more than 15%.[44] The symptoms are typical of tissue hypoxia, most notably neurologic impairment and myocardial dysfunction (the organ systems most vulnerable to hypoxia). There is no set combination of symptoms that confirms or rules out diagnosis of CO poisoning. The intensity of clinical manifestations varies and does not correlate closely with HbCO levels. Early signs tend to be neurologic. Central nervous system (CNS) injury can lead to progressive and permanent damage. Severe myocardial dysfunction may occur, especially in patients with preexisting coronary disease. The clinical diagnosis of HbCO poisoning should be confirmed by demonstrating its elevated levels. Elevated HbCO levels indicate significant exposure to smoke, which points to the likelihood of chemical airway injury. Low HbCO levels do not always mean minimal exposure, as oxygen therapy in the early stages can reduce levels during transport to the emergency department. Hypoxemia caused by CO poisoning is not detected by pulse oximetry or by partial pressure of oxygen (PaO_2) measurements, and patients may appear "cherry pink" rather than cyanotic. CO-oximetry is required to make the diagnosis. The binding of CO to hemoglobin is stable, with a half-life of 4 hours for a person breathing air.[45] Increasing the arterial PaO_2 accelerates the CO displacement from the hemoglobin molecule; administration of 100% oxygen at atmospheric pressure shortens the half-life to an average of 74 minutes.[46] Hyperbaric oxygen therapy has been suggested as a therapy to reduce the neurologic sequelae from CO toxicity. Hyperbaric oxygen therapy achieves faster CO displacement and may be more useful in cases of prolonged exposure, when it also may be assumed that it is harder to displace the toxin bound to the cytochrome system (e.g., mitochondria). The drawback of hyperbaric oxygen therapy is the need to transfer the burn injury patient to a treatment facility equipped with a hyperbaric chamber during the critical period of hemodynamic and pulmonary instability. For these reasons, it may be considered in patients with severe neurologic involvement and levels of HbCO greater than 50%, without extensive burns or severe lung damage, and whose symptoms fail to improve despite a high flow of oxygen. The lack of availability of hyperbaric oxygen poses a barrier to its use in many tertiary care centers.

Cyanide (CN) is released by the combustion of nitrogen-containing compounds, which are present in plastics, fabrics, and paper. CN acts by binding to cytochrome oxidase, thereby inhibiting the mitochondrial respiratory chain, cell metabolism, and tissue ATP production, resulting in cytotoxic hypoxia and metabolic acidosis. CN toxicity may have a synergistic effect with CO in producing tissue hypoxia. Concentrations of CN greater than 20 ppm are considered dangerous and concentrations of 100 ppm can lead to seizures, coma, respiratory failure, and death.[47] A rapid diagnostic test for CN poisoning is not widely available; as a result, the treatment of CN poisoning is generally based on clinical suspicion. CN poisoning should be suspected in any patient with a history of smoke inhalation injury with an anion gap metabolic acidosis in the presence of apparently adequate oxygen delivery. Lactic acidosis with a high anion gap can indicate CN poisoning, as can an arteriovenous oxygen saturation difference of less than 10 mm Hg because of the inability of the mitochondria to use tissue oxygen.[48] Lactic acidosis in burn victims may, however, be due to several causes and is not specific for cyanide toxicity. CN's short blood half-life (~1 hour) makes accurate determination of CN poisoning difficult and is hampered by delayed blood sampling.[49] Blood CO concentration is highly correlated with CN levels and as such, may be considered as an indicator of CN poisoning. Empirical treatment involves administration of high-flow oxygen. Specific antidotes are advocated, especially hydroxocobalamin, which binds to CN and is relatively nontoxic; but administration must be immediate for any effect to be useful.[50] The deleterious effects of CN can also be neutralized by the administration of thiosulfate converting CN to thiocyanate, which is excreted in the urine. Exogenous thiosulfate has a slower onset than hydroxocobalamin.[51] The treatment of CN toxicity by administration of nitrites (e.g., amyl nitrite) has generated controversy as this treatment in itself can be hazardous.[52] Nitrites induce methemoglobinemia which, together with HbCO, may interfere with oxygen transport, thus contributing to hypoxia.

DIAGNOSIS OF INHALATION INJURY

The diagnosis of inhalation injury is based on a combination of clinical findings such as patient history, physical examination, and HbCO levels. Patient history should include the duration of exposure such as whether the patient was found in an enclosed space, unconscious at the scene, or has extensive cutaneous burns. Physical findings include facial burns, singed nasal hair, signs of upper airway injury (hoarseness, stridor, carbonaceous sputum, erythema, and swelling of the oropharynx), and signs of lower airway involvement (dyspnea, tachypnea, wheezing, decreased O_2 saturations). Stridor, dyspnea, increased respiratory effort, and cyanosis appear only once critical narrowing of the airway occurs.

Chest radiographs lack the necessary sensitivity to detect lung damage for inhalation injury in the early stages, but their use is helpful as a baseline for determining future changes.[53] Fiberoptic bronchoscopy (FOB) offers a potential means by which to evaluate severity of inhalation injury although it may underestimate the presence of parenchymal disease and controversy exists over whether or not the visualized severity of the mucosal injury predicts clinically meaningful outcomes.[54] FOB is unnecessary if subglottic pathology is unlikely. In patients with clinical signs suggestive of thermal airway injury, a normal endoscopic appearance is reassuring although alveolar damage would not be revealed. FOB can be repeated at intervals or if there is clinical deterioration. The presence of soot, mucosal edema, mucosal hyperemia, and pooling of secretions indicates inhalation injury, and suggests the need for close observation with repeated assessment; more ominous signs include narrowing of the laryngeal inlet, mucosal erosion, ulceration, and exudation.[55] Virtual bronchoscopy is an alternative diagnostic modality to identify inhalation injury; however this is not widely practiced.[56] Other diagnostic methods include xenon scanning, pulmonary function testing, and computed tomography (CT).[57,58] The most reliable indicator of the impact of inhalation injury is the arterial partial pressure of oxygen to inspired oxygen fraction (PaO_2/FiO_2) ratio after the resuscitation has started.[59]

Laryngeal injuries are common in burn injury patients and can be associated with long-term morbidity.[60-63] Early recognition of laryngeal injury and consultation with a laryngologist can influence treatment choices (e.g., tracheostomy) and limit morbidity. Because anesthesiologists are most likely to view the larynx of patients with acute burns, it is important to make laryngeal examination part of the initial intubation whether during resuscitation or induction of general anesthesia. Any pathologic laryngoscopic findings should be documented.

TREATMENT

Treatment of upper airway burns secondary to smoke inhalation includes observation and monitoring.

Endotracheal intubation or tracheostomy is indicated if airway patency is threatened. Thermal injury to the oral cavity and supraglottic structures can cause edema; with severe injury, airway obstruction may result as a consequence of edema of the supraglottic airway. Clinically significant obstruction can also occur following fluid resuscitation, with maximal edema typically presenting hours after the initial insult and lasting for several days. There can be no substitute for patience and repeated airway assessment by an experienced anesthesiologist while minimizing edema formation by upright positioning and the avoidance of excessive fluid therapy. As a general rule, when indicated, it is safer to intubate the patient early than risk a difficult intubation after airway swelling has occurred. Although preemptive intubation of patients with inhalation injury can be lifesaving, it should be performed for clear indications. Reasons for intubation include: protection against anticipated airway swelling, treatment of impaired oxygenation and/or ventilation due to lung injury, and to ensure airway protection and optimal oxygenation in cases of hypoxia or CO poisoning with neurologic impairment. The treatment of pulmonary parenchymal injury is inherently more complex than treatment for cutaneous burns. Necrotic skin can be excised, and healing can be observed directly. In contrast, injured lung involves measures to prevent further injury to allow host mechanisms to repair injured tissues. Healing of pulmonary injury is followed indirectly by observations of blood gas analysis and radiographs/CT scans. Adequate oxygenation must be maintained and bronchial hygiene facilitated. Some patients may benefit from noninvasive ventilation in the absence of usual contraindications.[64] Endotracheal intubation may be necessary if the patient has increased work of breathing or if gas exchange is compromised.

Patients with both cutaneous burns and inhalation injury may require larger fluid volumes for resuscitation than those without inhalation injury.[65] Additional fluid resuscitation measures beyond titrating fluid input to maintain adequate urine output (generally considered 0.5-1 mL/kg/h) are not necessary and there are at least theoretical issues that the lung should be maintained "dry" to optimize gas exchange.[66]

Moderate elevation of the head of the bed allows gravity to help reduce airway edema by facilitating venous and lymphatic drainage, and is therefore a sensible, critical standard practice. The patient should be given oxygen by mask to maintain adequate arterial oxygen saturation. Suction should be used to keep the airway clear of debris and secretions. Children are at greater risk of obstruction because of their smaller airways, as are patients whose burns include circumferential burns to the neck. Other early signs and symptoms of respiratory dysfunction may be more suggestive of a more severe inhalation injury.

Respiratory failure is a consequence of inhalation injury; however, the severely burn-injured patient often has multiple mechanisms contributing to lung injury, systemic inflammation in response to burn injury, pulmonary edema from fluid resuscitation, and sepsis. Thus the extent to which inhalation injury impacts burn patient outcome is difficult to separate from the contributions of other injury drivers, which affect the lungs. Management of respiratory failure commonly consists of mechanical ventilation and effective and repetitive pulmonary toilet. A myriad of ventilation strategies exists, and consensus regarding the most appropriate way to ventilate patients with inhalation injury has not been reached.[67] In all cases, the goal of mechanical ventilation should be to optimize oxygenation and ventilation while minimizing potential ventilator-induced lung injury. The mechanisms of ventilator-induced lung injury include: high airway pressures causing barotrauma, over-distension of alveoli leading to volutrauma, repetitive opening and closing of alveoli causing atelectrauma, and lung inflammation caused by the release of proinflammatory cytokines that produce biotrauma.[68] The use of lung-protective ventilation strategies (i.e., tidal volume of 5-8 mL/kg predicted body weight, limitation of plateau pressure to less than 28 cm H_2O, and application of sufficient positive end-expiratory pressure to maintain alveolar patency and adequate oxygenation) is recommended as the initial approach if invasive ventilation is required. Studies have shown that lung protective ventilation with low tidal volumes are associated with lower mortality in patients with ARDS and are therefore also recommended in burn injury patients.[69] As in other critically ill patients, prone positioning has been shown to improve oxygenation in burn injury patients with severe ARDS.[70] Permissive hypercapnia, where blood carbon dioxide partial pressure ($PaCO_2$) is allowed to rise ($<$60 mm Hg) should be considered to limit plateau pressures unless there is a concomitant neurologic injury with suspected intracranial hypertension.[71] These lung-protective ventilation strategies are generally considered to also apply to pediatric patients, although some evidence exists to challenge this presumption.[72-74] Other strategies used by some burn centers for management of inhalation injury include high frequency percussive ventilation or high frequency oscillation ventilation, either of which may facilitate the clearance of airway debris and secretions.[75,76] High frequency percussive ventilation and high frequency oscillation ventilation may be considered as "rescue modes" in very severe lung disease, though a benefit on outcome remains unproven. Extracorporeal membrane oxygenation (ECMO) is increasingly used as a rescue treatment for patients with refractory hypoxemia but there is inadequate evidence to support its benefit in inhalation injury at this time.[78,79]

The consensus recommendations for mechanical ventilation also apply in this context, as do strategies for the prevention of ventilator-associated pneumonia.[80] Bronchodilators may be administered to help optimize ventilation in the event of bronchospasm. Bronchoscopy may improve pulmonary hygiene and patient prognosis by clearing secretions and sloughed epithelial cells. Although not yet in routine clinical use, there are several promising experimental pharmaceutical adjuncts that address physiologic changes associated with inhalation injury. Aerosolized racemic epinephrine serves as a bronchodilator, vasoconstrictor, and mucolytic agent to alleviate wheezing and bronchospasm caused by the chemical tracheobronchitis.[81,82] An aerosolized N-acetylcysteine/heparin combination therapy, which acts as both an oxygen free-radical scavenger and a mucolytic agent, has also been successfully used in children and adults with inhalation injury.[83-85] Inhaled nitric oxide causes selective vasodilation in ventilated lung segments, and may improve oxygenation and pulmonary hemodynamics.[86,87]

Noninvasive positive pressure ventilation (NIV) has been successfully used to avoid endotracheal intubation in select patients with mild inhalation injury with little evidence of edema, or as respiratory support strategy following extubation.[88,88a] The potential benefits of NIV are numerous including allowing the patient to communicate freely, require less sedation, allow cough and expectoration of secretions, and avoid other potential complications of intubation such as oropharyngeal trauma, mucosal ulceration, and ventilator-associated pneumonia. However, very strict case selection is essential. NIV requires compliant patients who can cough and protect their own airway and it must not be used where there is a risk of airway obstruction, or in patients with facial burns because of the tight mask required. In addition, there are legitimate concerns that NIV may conceal signs of progressive airway obstruction in the setting of an inhalation injury. The use of opioid and sedative drugs, often needed in burn injury patients, may complicate the use of NIV as a consequence of their respiratory depressant effects.

High-flow nasal cannula is a mode of respiratory support increasingly used in the management of acute respiratory failure. This mode delivers humidified gas via a nasal cannula at flow rates exceeding minute ventilation. The benefits include the reduced work of breathing and improved gas exchange by nasopharyngeal dead-space washout; decreasing the energy required to humidify and heat respiratory gases; and providing a degree of positive distending pressure. There are limited reports of its use in patients with inhalation injury.[89]

Acute Management

PATIENT EVALUATION

Optimal management of burn injury patients begins at the scene of injury and continues in the emergency department and with transfer to a specialized burn unit. The primary survey should be performed using a systematic approach that first seeks to identify the greatest threats to life as provided in the Advanced Trauma Life Support (ATLS) and Advanced Burn Life Support (ABLS) guidelines.[90,90a] This approach requires a combined strategy of airway assessment and protection, initiation of resuscitation, and evaluation for coexisting injuries. Protecting the airway of a thermally injured patient is of the utmost priority. Early intubation is indicated in patients with symptomatic inhalation injury, or any thermal injury to the face, mouth, or oropharynx that threatens airway patency (stridor, swelling on laryngoscopy, upper airway trauma, altered mentation, and respiratory distress).[91] The current criteria for prehospital intubation has been questioned because of the high incidence of over-intubation and early extubation posthospital admission.[92] Despite this concern, it seems safer to intubate and modify therapy once in hospital rather than be afflicted by airway distress during prolonged transport. Oropharyngeal burns can rapidly cause obstruction; other causes of critical respiratory failure, such as coma, require immediate diagnosis and treatment. Once the airway is secure, breathing assessment follows. Auscultation of breath sounds and determination of respiratory rate and depth are essential for assessing the status of the lungs, chest wall, and diaphragm, and to evaluate the patient's ability to adequately ventilate and oxygenate. Circumferential burns of the trunk or neck may impair respiration and require bedside escharotomy. Continuous monitoring of heart rate, blood pressure, pulse oximetry; and clinical assessment of unburned skin color should be used as parameters to assess circulatory status. An elevated heart rate (100-120 beats/min) is considered within normal limits for adults with burn injury; a higher heart rate should raise suspicion for hypovolemia, other trauma, and inadequate pain management. Circulatory assessment requires evaluation of perfusion of all extremities, paying particular attention to any circumferentially burned extremities. If perfusion is compromised, escharotomy is indicated. Intravenous access should be obtained via peripheral, central, and/or intraosseous routes and may safely be placed through burned tissue if necessary. Adjuncts such as ultrasound may be helpful in placing peripheral intravenous catheters. Large-bore peripheral access is preferred because smaller catheters do not allow faster fluid administration, especially in larger burns.

Fluid management based on weight and burn size should be addressed once total assessment of the injury has been established. Patients who have sustained a thermal injury often present with altered mental status and the possibility of associated injury, substance use, hypoxia, inhalation injury, or a preexisting condition that should always be addressed. As with trauma patients, the Glasgow Coma Scale, which utilizes verbal, motor, and eye measurements, can be used to establish a baseline mental status. Providing adequate environmental temperature control is essential for burn injury patients as they lose their ability to thermoregulate. The patient must be completely exposed to assess injury and to remove any contaminants that might prolong contact with chemicals or heat sources. A warmed environment and immediate coverage with clean blankets can limit hypothermia during the examination. More than 5% of patients admitted to burn centers have also sustained nonthermal traumatic injuries.[93] Therefore all burned patients should be approached initially as multiple trauma patients. Whole-body CT imaging and focused assessment with sonography in trauma-echocardiogram exam should be performed when associated injuries are suspected.

Indicated imaging, laboratory analyses, and adjunctive measures such as urethral catheters and nasogastric tubes should be completed at this time. It is mandatory to perform a rapid primary evaluation and immediately correct any problems found. Once these steps are completed, a more thorough assessment of thermal injury may ensue. The patient's full history should be taken including: detection of the mechanism of injury, consideration of abuse, height and weight, possibility of CO intoxication, and facial burns. In addition, history of previous diseases should be obtained, if possible (allergies, medications, past medical history, events).

Once the primary and secondary surveys have ensured stabilization of the thermally injured patient, transfer to a facility capable of providing the care necessary to support a burn patient is initiated. The American Burn Association has criteria for referral to a specialized burn center that includes both patient and burn characteristics such as size, depth, and etiology (Box 87.1).[94] Patients who should be referred to a higher level of care for burns include those with partial thickness (second degree) burns greater than

BOX 87.1 **American Burn Association Burn Center Transfer Criteria**

- Second- and third-degree burns on >10% of TBSA in patients age <10 or >50 years
- Second- and third-degree burns on >20% of TBSA in other age groups
- Second- and third-degree burns that involve the face, hands, feet, genitalia, perineum, and major joints
- Third-degree burns on >5% TBSA in any age group
- Electrical burns, including lightning injury
- Chemical burns
- Inhalation injury
- Burn injury in patients with preexisting medical disorders that could complicate management, prolong recovery, or affect mortality
- Any patients with burns and concomitant trauma (such as fractures) in which the burn injury poses the greatest risk of morbidity or mortality; in such cases, if the trauma poses the greater immediate risk, the patient may be treated initially in a trauma center until stable before being transferred to a burn center
- Hospitals without qualified personnel or equipment for the care of children with burns should transfer the patient to a burn center with these capabilities
- Burn injury in patients who will require special social/emotional and/or long-term rehabilitative support, including cases involving suspected child abuse and substance abuse

TBSA, Total body surface area.

10% TBSA; those with burns of the face, hands, feet, genitals, perineum, or across major joints; and those with full thickness (third degree) burns of any size. Evidence suggests that burn injury patients have improved outcomes if transferred early to a facility capable of providing an advanced level of burn care.[95,96] Therefore it is important to accurately identify those patients with burns severe enough to merit transfer so that outcomes will be optimized.

Burn centers have been developed to standardize and optimize the overall quality of care delivered to burn-injured patients.[97] Burn centers provide acute care using a multidisciplinary team that includes burn surgeons, anesthesiologists with special interest in burns, critical care physicians, burn-trained nurses, physical and occupational therapists, pharmacists, and dietitians. In addition, improvements in burn survivors' long-term functional and psychological outcomes and quality of life have resulted from burn units having integrated relationships with physiatrists and rehabilitation facilities as well as burn psychologists and exercise therapists. Since an important part of functional recovery includes returning to work or school, newer additions to the burn team include vocational counselors, recreational therapists, child life specialists, and teachers.

Estimation of Size and Depth of Burn Injury

The magnitude of burn injury is classified according to the percentage of total body surface area (%TBSA) involved, depth of the burn, and the presence or absence of inhalational injury. Accurate estimation of burn magnitude is needed to guide the initial resuscitation strategy, make the referral to a burn center, ascertain the need for surgery, and to estimate prognosis.[98] Whereas a detailed evaluation of the extent of the thermal injury is assessed during the secondary survey, an early estimate of burn size and depth is needed during the primary survey to calculate initial resuscitation fluid requirements for circulatory support. Three of the most commonly used methods to estimate %TBSA are the "rule of nines," palmar surface area, and the Lund-Browder diagram. The rule of nines is used in adults and is less accurate in children. This method divides the body into body surface areas of 9% (the head, each upper limb, the front of the trunk, the back of the trunk, the front of each lower extremity, and the back of each lower extremity).[99] The surface area of the patient's palm (excluding the fingers), approximately 0.5% of the TBSA, is used to estimate small (<10% TBSA) burns.[100] However, this method is inaccurate for larger burns. The Lund-Brower diagram is considered the most accurate, if used correctly (Fig. 87.2).[101] It allows for the variation in body proportions with age and is used especially in children. Computerized methods have evolved and demonstrate high correlation and reproducibility.[102]

Burn depth is also considered an important determinant of outcome. First-degree burns are limited to the outer layer or epidermis of the skin. The skin usually appears red and dry and is very painful to touch. Healing takes place in 3 to 5 days. Second-degree burns are further categorized into superficial and deep partial thickness burns. A superficial partial thickness burn extends into the superficial papillary dermis and appears red in color with significant weeping and blisters. It will also blanch when pressure is applied, and generally it takes less than 2 weeks to heal. Deep partial thickness burns extend into the reticular dermis and appear yellow or white and dry and often are extremely painful; however, in some cases, the sensation in the deep partial thickness may become diminished. Full thickness or third-degree burns extend through the entire thickness of the dermis. These may appear dry, leathery, black, or white and are usually painless since nerves and endings are destroyed. They do not blanch under pressure. Although initially painless, the subcutaneous inflammation associated with deep dermal burn often becomes more painful than more superficial burns.[103] The designation, fourth-degree burns, is used to describe those that have injured deeper structures, such as muscle, fascia, and bone. Deep second-, third-, and fourth-degree burns require surgical debridement and grafting, whereas more superficial burns do not. Since the area of injury may progress over the first 2 to 3 days after the initial insult due to the effects of coagulation and ischemia, burn depth estimation may be greater when examined later compared to the initial evaluation. Close reevaluation may be required to determine the actual burn size and depth.

Fluid Resuscitation

Current fluid therapy is based on knowledge gained over the last century. Major breakthroughs in fluid management were made by Underhill, who described the pathophysiology of burn injury in detail in the 1920s.[104] In 1940, after the Coconut Grove night club disaster in Boston, Massachusetts, the first attempts were made to use intravenous fluids to treat a large group of burn injury patients, and the result was that the mortality was significantly lower than expected. In 1953, the first fluid formula based on the size of the burn and the patient's weight was introduced by Evans.[105] The formula most widely used today is the one that was published in 1974 by Charles Baxter, who was then working at the Parkland Memorial Hospital in Dallas, Texas. The Parkland formula calls for 4 mL/kg/%TBSA of Ringer lactate solution given over the first 24 hours, half of which is given within the first 8 hours from the time of injury.[106] The main advantages of the Parkland formula are use of an easily obtainable fluid (Ringer lactate), low cost, and a strategy that is easy to start and follow. A number of other formulations have been reported over the years, but none has the global impact of the Parkland formula. Some of the more common options are listed in Table 87.1.[107,108]

Today, few centers in Europe or the United States use formulations other than the Parkland initially.[109] Appropriate resuscitation should be initiated promptly and tailored based on patient parameters to avoid over- and under-resuscitation. Delayed or inadequate fluid replacement results in hypovolemia, tissue hypoperfusion, hypovolemic shock, and multiple organ failure. Morbidities associated with over-resuscitation include pulmonary edema, compartment syndromes (muscle compartments, abdomen, and the orbits), and even cerebral edema. As a general rule, burns of less than 15% TBSA can be managed with oral or intravenous fluid administered at 1.5 times maintenance rate (Box 87.2) and careful attention to hydration status. Maintenance fluids, including a source of glucose, should be added to pediatric patient resuscitation fluid as hepatic glycogen stores will be depleted after 12 to 14 hours of fasting.[110]

Fig. 87.2 Lund-Browder burn diagram and table. The Lund-Browder burn diagram and table indicate the varying proportions in surface area in persons with different ages. A careful burn diagram should be completed at the time of initial evaluation, including wound size, location, and estimated burn depth. The Lund-Browder chart should be used in pediatric patients because the body surface area relationships vary with age. *TBSA*, Total body surface area.

Later, when insulin resistance and associated hyperglycemia develops, glucose infusions should be modulated. Colloids have the potential to increase oncotic pressure and thereby reduce fluid shifts and losses. Controversy remains as to the ideal time for initiation of colloid therapy in burn resuscitation. There is a general trend now to initiate colloids earlier than the previously recommended time of 24 hours.[109] All the formulae guide resuscitation with the goal of titrating fluids to obtain a urine output of 0.5 mL/kg/h in adults and 1.0 mL/kg/h in children. The reasons for using hourly urine output are that it is easily measured (once a Foley catheter has been placed), it reflects glomerular filtration rate and renal blood flow, and it is a surrogate for end-organ perfusion and an indirect correlate of cardiac output.

ENDPOINTS FOR THE FLUID TREATMENT

No matter which formula is used, it should serve only as a guideline, and fluid resuscitation should be titrated to physiologic endpoints. However, the optimal hemodynamic

TABLE 87.1 Formulations for Fluid Treatment

Formulation	Contains
Parkland	Ringer lactate solution 2-4 mL/kg/TBSA% Half the fluid volume given during the first 8 h and the remainder during the next 16 h
Modified Brooke	Ringer lactate solution 2-4 mL/kg/TBSA%
Brooke	Ringer lactate solution 1.5 mL/kg/TBSA% + colloid 0.5 mL/kg + 5% glucose solution 2000 mL/24 h. The PiCCO instrument measures colloid can be albumin or fresh frozen plasma
HYPERTONIC SOLUTIONS	
Monafo	Ringer lactate containing sodium 250 mmol/L. Volume sufficient to produce urine 30 mL/h. Not commonly used in view of the hyperosmolar effects

BOX 87.2 Maintenance Fluid for Children

- 100 mL/kg up to a body weight 10 kg
- Above 10 kg weight, 50 mL/kg are added in the weight range of 11-20 kg
- Above 20 kg weight, add 20 mL/kg for every kg
  Example: Maintenance fluid for a child of 28 kg:
  1000 mL + 500 mL + 160 mL, i.e., total 1660 mL/24 h

targets of initial resuscitation in burn injury patients remain largely unknown. While traditional markers such as blood pressure, urinary output, and cardiac output are helpful, they do not sufficiently reflect the adequacy of regional perfusion and microcirculation. Even when macrocirculatory variables are within therapeutic goals, signs of tissue hypoperfusion may persist.[112] Furthermore, microcirculatory alterations have been identified in patients with severe burns, and the severity of these alterations has been associated with a poor outcome.[113]

In an effort to address deficiencies in regional tissue perfusion and microcirculation, trials of "goal-directed" resuscitation have been undertaken, in which fluids are increased to normalize acidosis or achieve normal levels of cardiac output or oxygen utilization.[114,115] This approach initially seemed effective but, in subsequent analyses, has not proved superior to traditional resuscitation, and resulted in administration of increased fluid volumes and the associated complications. This experience has confirmed earlier studies showing that cardiac output and other parameters require 18 to 24 hours to normalize following burn injury no matter what resuscitation strategy is employed.[116] Therefore it appears that the optimal resuscitation strategy is to maintain the burn injury patient in a controlled hypovolemic state with an aim to maintain a urine output of 30 to 50 mL/h in adults. Central circulatory variables, such as intrathoracic blood volume index (ITBVI) when using a Pulse Index Contour Continuous Cardiac Output (PiCCO, Pulsion Medical Systems, Germany) system, wedge pressure when using a pulmonary artery catheter, or stroke volume/cardiac output with echocardiography, should indicate hypovolemia during this specific period. The PiCCO instrument measures cardiac output and extravascular lung water by thermodilution. Hence leaky lungs from inhalation injury and during ventilation-perfusion abnormalities it may give incorrect estimates of cardiac output and extravascular lung water, respectively. When assessing circulation 18 hours after the injury, these central variables of cardiac filling and function will normalize with this resuscitation strategy.[116]

During the last few years, there have been indications that an increase in under-resuscitation of burn injury patients may be occurring.[118] In addition, a recent survey of resuscitation strategies in Europe suggests an increase in the use of vasopressors and inotropes and early use of colloid for burn injury patients.[119] While the impact of these changes remains unknown, there are two important issues using such a strategy. First, the skin, which in burn injury is the damaged organ, has a very high density of α1 adrenoceptors in its vascular bed and secondly, this compartment receives a significant portion of the fluid volume provided by resuscitation, thereby significantly increasing the risk of progression of the burn wound from second- to third-degree injury. There is scientific evidence in humans that support skin ischemia in edematous tissue after fluid resuscitation and this may be assumed to be a significant risk for deepening of the burn wound.[120]

FLUID CREEP/RESUSCITATION FAILURE

A small percentage of patients fail to respond to conventional fluid resuscitation. Signs of resuscitation failure include low urine output, repeated episodes of hypotension or need for vasopressors, worsening of base deficit, or fluid infusion in excess of predicted resuscitation needs in the first 24 hours.[121] When the fluid requirements exceed that calculated by the Parkland formula, administering either albumin or plasma (colloid rescue treatment) instead of or in conjunction with the crystalloid is often recommended to reduce the risk of compartment syndrome.[122] The risk of abdominal compartment syndrome (ACS) increases appreciably when fluid volumes greater than 250 mL/kg/24 h are exceeded.[123]

If the total fluid requirement exceeds 6 mL/kg/%TBSA per 24 hours, it is advisable to obtain more information regarding intravascular volume and cardiac function. This usually occurs with very deep burn injury beyond the dermis. Hemodynamic monitoring modalities to obtain this information on cardiac function include transthoracic and/or transesophageal echocardiography, measures of cardiac preload or fluid responsiveness (e.g., stroke volume variation, ITBVI or pulmonary arterial wedge pressure, cardiac index), measures of oxygen delivery and/or consumption (e.g., central venous oxygen saturation [$ScvO_2$]), serum markers (e.g., base deficit, lactate), and measures of cellular metabolism (e.g., gastric tonometry). The major limitation of routinely using these measures for all resuscitations is that they have not been validated as resuscitative endpoints in the burn injury population; targeting multiple endpoints may result in excess fluid administration.

With large volume resuscitation, monitoring of abdominal, ocular, and extremity-fascial compartments for hypertension should regularly be performed. The most commonly used method to monitor intraabdominal pressure is measurement of intravesical pressure through a catheter inserted in the urinary bladder. The normal range of intraabdominal pressure is less than 5 to 12 mm Hg. Values above 25 mm Hg generally necessitate intervention, whereas values between 12 and 25 mm Hg indicate the need for close observation for evaluation.[124,125] ACS is defined as sustained intraabdominal pressure exceeding 25 mm Hg with new-onset organ failure, such as oliguria or decreased lung compliance. It should also be suspected not only in patients with major burns but particularly in those who have received an amount of fluid resuscitation well beyond that predicted based on weight and burn size. In cases of symptomatic intraabdominal pressure or ACS, decompression is necessitated via paracentesis, laparoscopy, or laparotomy.

"Fluid creep" refers to the trend of over-resuscitation in burn injury patients.[126] Overly aggressive fluid administration may result in pulmonary edema, compartment syndromes, multiorgan failure, nosocomial infection, and increased mortality as well as the extension of the burn injury because of excessive local edema.[127] Factors that contribute to "fluid creep" include overestimation of the burn size, emphasis on achieving supra-physiologic hemodynamic targets (e.g., base deficit, lactate, cardiac index and/or output, and surrogate markers, such as stroke volume variation), and increased opioid utilization (opioid creep).[128,129] A hesitancy for reducing the rate of fluid administration in patients with evidence of adequate tissue perfusion such as a urine output greater than 0.5 mL/h in adults or greater than 1.0 mL/kg in children also appears to play a role in fluid creep.[130] Computerized decision-support tools may be beneficial to decrease the volume of crystalloid infused and, consequently, the incidence of fluid creep and its complications.[131] Such systems reduce over-resuscitation by rapid downward titration of fluid volumes when urine output is adequate.

Strategies to limit fluid creep may include albumin administration during early resuscitation and, more commonly, initiation of "colloid rescue" early (12-24 hours) after the burn injury when capillary integrity is thought to be restored. Hypertonic saline may also be beneficial in limiting fluid volumes, but careful monitoring is needed, as hypernatremia is associated with the development of acute renal failure.[132,133] High-dose ascorbic acid (vitamin C) may have efficacy in reducing resuscitation volumes and the time to complete resuscitation in severe burns.[134,135] Its use has not gained traction because of concern for osmotic diuresis and renal failure as well as an association with pseudohyperglycemia.[136] Exchange transfusion (plasmapheresis) has been attempted but is not currently used.[137]

Electrical Injury

Electrical burns account for up to 4% of admissions to burn centers.[138] The severity of injury after an electrical burn depends on voltage (V), current, type of current (alternating or direct current), path of current, duration of contact, resistance of involved tissues, and individual susceptibility.[139] Low-voltage electrical injury is classified as less than 1000 V and can damage tissue at the contact site. High-voltage injury is characterized as more than 1000 V, and leads to damage that extends into the surrounding tissues, particularly to muscle around long bones. Exposure to current generated may also cause cutaneous injury by transformation of electrical energy to thermal energy. Injuries can range from local erythema to full-thickness burns. Burns due to lightning are common but typically quite superficial because of the short duration of contact between the energy source and the victim.[140]

Electrical injury should be managed as a multisystem injury. Evaluation for associated traumatic injury, particularly to the spinal cord, should take place, including assessment for event-associated blunt thoracic or abdominal trauma.[141,142] Patients with high-voltage injuries should also be evaluated for rhabdomyolysis. Limbs should be assessed for compartment syndromes that may require fasciotomy. For treatment of these complications, patients may come to the operating room within 24 hours of injury. In high-voltage electrical injuries, urgent surgery may be life-saving, and is necessary to allow the highest chance for limb salvage. After initial burn wound excision, further debridement may be indicated to ensure adequacy of excision of necrotic tissue before reconstruction. Wound management of high-voltage injuries often requires staged debridement, because the extent of myonecrosis is often difficult to initially ascertain and myonecrosis can extend over time. Wound closure often requires use of grafts and local or distant flaps. High-voltage electrical injuries can be severe resulting in the need for amputations. The tetanic contraction of muscle caused by continued electrical stimulation may cause bone damage including vertebral fractures.

Electrical injury affects the cardiovascular system by directly causing necrosis of the cardiac muscle and by inciting dysrhythmias.[143] The most frequently encountered rhythm disturbance is sinus tachycardia, often accompanied by nonspecific ST- and T-wave changes. Conduction defects such as heart blocks are also common. Cardiac standstill and ventricular fibrillation are the most serious cardiac complications of electrical injury. Patients without electrocardiographic changes on presentation are unlikely to experience life-threatening arrhythmias.[144] The myocardial injury after electric shock behaves more like a cardiac contusion than a myocardial infarction generally with minimal hemodynamic consequences. Enzyme markers of cardiac injury may be misleading, as normal enzyme concentrations in the circulating blood do not exclude the possibly of a conduction system injury with consequent rhythm disturbances.[145]

Patients with major electrical burns should have an individualized fluid resuscitation. Deep tissue injury, including visceral injury with extravasation into extravascular compartments, makes formula-based resuscitation generally inadequate since the surface burn is only a portion of the injury.[146] In addition, the current-induced injury to muscle can lead to rhabdomyolysis and myoglobin release, which can precipitate in the renal tubules causing acute kidney injury. Thus if myoglobinuria is present, urine output should be maintained at 1 to 2 mL/kg/h until the urine is no longer pigmented, at which time urine output can be titrated to 1 mL/kg/h.[147] Additional treatment with sodium bicarbonate, mannitol, and furosemide facilitate myoglobin excretion and protect against renal tubular injury. It is not uncommon for patients with major electrical burns to suffer long-term neuropsychological sequelae such as chronic pain and therapy-resistant psychological symptoms that need to be addressed in an extended rehabilitation process.[148]

Chemical Burns

Chemical burns represent only about 3% of burn center admissions, but they are an important source of morbidity.[138]

Most chemical burns in middle- or high-income countries occur in the workplace, but some are secondary to assault, typically to the face. Chemical injuries have some important biochemical differences when compared to thermal burns. In thermal injuries, there is a rapid coagulation of tissue protein due to irreversible cross-linking reactions, whereas in chemical burns the protein destruction continues longer due to hydrolysis mechanisms.[150] These mechanisms may extend as long as traces of the offending agent are present especially in deeper skin layers. In addition, some chemical agents can produce a systemic toxicity. The duration of the chemical's contact with skin is the major determinant of injury severity. The severity of a chemical burn injury is also determined by the concentration of the agent, its tissue penetration, and mechanism of action.[150]

The initial management of any chemical exposure is to eliminate the toxic chemical quickly without contaminating care providers. Elimination of the toxic chemical involves removal of clothing and a thorough irrigation with water.[152] In most instances, efforts to neutralize chemicals are contraindicated due to the additional generation of heat, which would further contribute to tissue damage.[153] Dilution, not neutralization, is the key to therapy. There are two notable exceptions: hydrofluoric acid (sub-eschar injection of 10% calcium gluconate) and white phosphorous (lavage with 1% or 2% copper sulfate immersed in water).[154] Diphoterine is a new chelating agent that has shown initial promise for treatment of chemical burns.[155] The insidious nature of some chemical injuries allows them to progress for prolonged periods so that an initially superficial-appearing wound ultimately requires surgery. A special concern in larger settings of chemical accidents are precautions not to contaminate the emergency department by the chemical in question. Initial cleansing of the chemical is performed outside the hospital doors and such procedures should have an action plan in the hospital disaster management protocols.[156]

General support and care involves fluid resuscitation as with a burn injury using urine output monitoring to assess adequacy of end-organ perfusion. Disturbances of pH can occur with systemic toxicity.[153] Blood gas and electrolyte analysis should be performed until metabolic disorder has been treated and controlled. After lavage and debridement, chemical burns can be treated with topical antimicrobial agents and dressings. Early excision and grafting may be needed albeit the pronounced difficulties in assessing burn depth in these injuries. Inhalation injury may also occur and be present if chemicals are aerosolized and such injuries are managed like smoke inhalation injuries.

Cold Injury

Cold injury or frostbite occurs when tissues are exposed to temperatures below their freezing point (typically −0.55°C) for a sustained period of time.[158] Severity of injury depends on a number of factors including the absolute temperature, duration of exposure, wet or dry cold, immersion, and patient comorbidities such as peripheral vascular disease, neuropathies, smoking, mental health issues, and substance abuse.[159]

Cold injury most commonly occurs in the distal extremities or exposed areas of the face. It can result in a wide spectrum of injuries, ranging from minor injury with complete resolution to the need for major limb amputation. The progression of cold injury evolves over time. The wounds may initially present with blisters that do not appear to be deep. Over days to weeks, because of injury to the microvasculature, they can progress to full-thickness loss; toes and fingers may mummify over prolonged periods.

On arrival to the hospital setting, underlying unstable comorbidities, trauma, or hypothermia must be assessed and managed before frostbitten extremities are treated. Moderate or severe hypothermia should be corrected to bring core temperature above 35°C before initiating frostbite warming. Rewarming the extremities can become extremely painful, so analgesics should be administered.[160] Rewarming is ideally accomplished using a whirlpool bath set at a temperature range of 37°C to 39°C, which decreases the pain experienced by the patient while only slightly slowing rewarming time. Rewarming should continue until a red/purple color appears and the extremity tissue becomes pliable. Loss of sensation after a long period of normothermia is a poor prognostic indicator.[158]

If ischemic frozen extremities do not reperfuse after rewarming, early angiography, thrombolysis, and anticoagulation may be warranted.[162,163] Intravenous vasodilators (nitroglycerin or papaverine) may be useful in conjunction with thrombolysis to address the vasospasm that often accompanies a frostbite injury. Magnetic resonance angiography may be beneficial for prognostication as it allows direct visualization of occluded vessels and surrounding tissue and may show a clearer demarcation of ischemic tissues.[163] Wound management is generally conservative, allowing ischemic tissues to demarcate before excision. Wound closure often requires skin grafts and local or distant flaps. Prophylactic antibiotics are not indicated since frostbite injuries are not inherently tetanus-prone wounds.

Stevens-Johnson Syndrome/Toxic Epidermal Necrolysis

Toxic epidermal necrolysis syndrome (TENS) and Stevens-Johnson syndrome (SJS) are severe exfoliative diseases of the skin and underlying structures caused by immunologic reactions, usually triggered by a medication or a viral syndrome.[165] Common triggers for SJS and TENS are drug exposure with anticonvulsants, antibiotics, and allopurinol.[166] The two syndromes are distinguished from each other by disease severity, which is characterized by the extent of epidermal detachment and erosions of mucous membranes. The TBSA involved in SJS is less than 10%, 10% to 30% in SJS-TENS overlap, and more than 30% in TENS. Outcomes vary according to the TBSA affected and age. Mortality with TENS is approximately 15% whereas that of SJS is less than 5%.[167] Age, as in thermal burns, is also a major factor affecting outcome in these patients.[168] The primary cause of death is infection and multiorgan failure. Because a burn center has personnel with expertise in the management of patients with skin loss from thermal injury, it often provides care for patients with SJS and TENS. Initial treatment begins with withdrawal of any offending drug and includes airway protection if needed, fluid resuscitation, nutritional support, close monitoring for septic complications, and eye care.[169] Wound desiccation and superinfection is prevented with topical antimicrobial agents, and selective use of wound membranes can also be considered. Numerous other adjuvant therapies have been tried in TENS management including corticosteroids, cyclosporin, cyclophosphamide, plasmapheresis, pentoxifylline, *N*-acetylcysteine, ulinastatin, infliximab, and granulocyte colony-stimulating factors (if TENS-associated leukopenia exists); however their effectiveness is uncertain.[170]

Special Considerations

PEDIATRICS

The treatment of children with burn injury differs from burn care in adults in several areas, including airway management, fluid resuscitation, and pharmacologic therapies.[171] Children have a greater body surface area to mass ratio than adults, resulting in increased fluid resuscitation requirements (based on body weight), greater evaporative water, and making them more prone to hypothermia. In addition, children have disproportionately thinner skin, which may lead to the risk of deeper burns at lesser temperature. Thinner skin also makes initial burn depth assessment difficult because a burn may initially appear to be of partial thickness but be a full thickness injury or can develop into a full thickness injury.

The circulatory system in infants and children also differs from that of adults. Infants have limited cardiac contractility and are dependent on their heart rate to increase cardiac output. In addition, there is a greater susceptibility to fluid overload, especially in younger children, particularly if all the administered fluids (flush solutions, medications, carrier fluids) are not taken into account. During surgical procedures, it is important to account for the volume of fluid administered subcutaneously for tumescence of donor sites and burn sites. The kidneys of young infants have less concentrating ability. The short length of pediatric intravenous catheters and patient activity can lead to extravasation as the patient develops edema after burn injury. Central lines in children can compromise circulation to extremities and require extra monitoring. Intraosseous lines can result in limb loss due to compartment syndrome from either a misplaced or dislodged catheter, or leakage of infused fluids around the needle insertion site.

The child's body temperature should be closely monitored and ambient temperature increased in the examination room to prevent hypothermia. Warm intravenous fluids and warm blankets are useful adjuncts in this setting. Fluid-based convection heat mattresses can be particularly effective and useful in this scenario. Wet cold dressings and cold intravenous solutions should be avoided to decrease loss of body heat.

Airway and pulmonary considerations in children include their smaller airway, which can rapidly be compromised with airway edema causing resistance to airflow. Infants and small children also lack the pulmonary reserve present in older children and adults. In children with scald injury, respiratory failure can occur during and after fluid resuscitation, even in the absence of inhalation injury.[172] Stridor and retractions should be taken as signs of airway compromise and a need for intubation. Asthma is prevalent in children and may be exacerbated by smoke inhalation. Bronchospasm, common in children suffering inhalation injury, should be treated early and aggressively.

Children are susceptible to resuscitation-related cerebral edema, which can result in seizures or brain herniation.[173,174] There is laboratory evidence that the blood brain barrier may be more easily disrupted in children after major burn injury and could thus lead to a larger risk for neurologic dysfunction.

Assessing pain and anxiety is challenging in children because many are unable to verbalize their complaints. Compared to adults, opioid tolerance seems to develop faster in young children.[175] Age-specific pain and anxiety scales exist and should guide care. In general, a child should be upset and crying after burn injury. A moribund or minimally responsive child is likely to be in shock and requires immediate attention. Children are often combative during wound care and dressing changes. During these times, appropriate doses of anxiolytics and analgesics, including ketamine and benzodiazepines, should be administered. However, once the stimulus stops, special attention is needed as children can be oversedated because the half-life of the drug is longer than the duration of painful dressing changes.

Up to 20% of pediatric burn injuries are a result of abuse or neglect. Abuse should always be considered in a child with burn injury, particularly when the injury pattern does not match the history given, in the presence of multiple injuries of different durations, or in cases when there is evidence of delay in seeking treatment. Physical examination indications such as uniform burn depth with sharp borders; symmetrical isolated lower limb and buttock injury; skinfold sparing; absence of splash marks; associated unrelated injuries; and a passive, introverted, fearful child should also raise suspicion and trigger screening by dedicated child abuse teams.

ELDERLY

Older individuals are more vulnerable to burn injury and are less able to compensate from the injury when it occurs.[176,177] Age is the most important outcome factor besides TBSA. Concurrently, mortality rate, as well as severity of complications, is more pronounced in this group of patients. The propensity of geriatric patients to burn injury is likely the result of impaired dexterity and mobility, impaired vision, and decreased coordination, which also impair their ability to react rapidly and reach safety when faced with danger.

Older adults often have more comorbid medical conditions and therefore take multiple medications that may blunt their response to the physiologic stress of burn injury and increase their risk for complications. Coexisting cardiac and pulmonary disease can result in complications related to fluid resuscitation including pulmonary edema, congestive heart failure, and pneumonia. Close monitoring of respiratory and cardiovascular parameters in older adults is mandatory during fluid resuscitation. The decision to resuscitate should be carefully weighed in older patients with large cutaneous burn injuries, especially in the presence of inhalation injury, because mortality rates can exceed 90%.[178] Advanced directives, healthcare proxies, and families should be consulted as early as possible.

Older burn injury patients have a lower threshold for ventilator support during treatment because of the decrease in lung reserve. Preexisting renal disease can result in greater sensitivity to nephrotoxic drugs. Older patients also have an altered and impaired immune-response and thereby an increased susceptibility to infection.[179]

The skin of older patients is thinner and more susceptible to deeper burn injury. In addition, there is impaired capacity for dermal and epidermal regeneration, so harvesting and especially repeated harvesting of donor skin may not be possible because of poor wound healing. Under normal circumstances, older patients have a reduced resting metabolic rate and may be unable to generate the required increase in metabolic response following a burn injury. For even a minor burn injury, they may benefit from nutritional support and may gain benefit from nutritional rehabilitation prior to surgical treatment.[180] Care should be taken with enteral feeding as it poses a risk of aspiration, particularly in delirious older burn victims. Pain control in the older patient is often inadequate following burn injury, and the premise that there is less pain with increasing age is without foundation.[181] Finally, older patients may live alone or have a spouse who is unable to provide the care needed after discharge, including wound care, transportation, and support.

OBESE PATIENTS

Management of the morbidly obese patient poses many clinical challenges including accurate measurement of burn size, resuscitation requirements, mechanical ventilation settings, drug dosing, mobilization, and effective nutritional goals. During resuscitation, obese burn injury patients take a longer time to reach end points of resuscitation and normalize their metabolic derangements.[182] This finding is consistent with findings in the trauma literature in the obese population.[183] This group can have persistent metabolic acidosis during the resuscitation phase and are at greater risk of developing more severe multiple organ failure.[182] These factors may contribute to higher mortality risk in the morbidly obese burn patient.[182,185] It remains unclear as to whether actual or ideal body weight is appropriate for estimating fluid requirements accurately. The use of actual body weight to drive resuscitation volumes may result in over-resuscitation of these patients, depending on the resuscitation formula.[187] However, actual body weight and TBSA provide a reasonable starting point, after which fluid rates should be reduced hourly to meet individual needs while preventing burn shock or other complications. In contrast to morbid obesity, mild obesity, for reasons unclear, seems to have a better survival.[188]

Infection Control

Infection is a leading cause of morbidity and mortality in burn injury patients because of their increased susceptibility to infection through multiple mechanisms, including altered immunity, loss of the physical barrier of intact skin, damage to the lining of the respiratory tract from inhalation injury, altered gut permeability, and invasive devices. These devices include endotracheal tubes (ETTs), intravascular catheters, and urinary catheters, which bypass the body's normal defense mechanisms. Sources of organisms that can cause hospital-acquired (nosocomial) infection include the patient's endogenous flora, exogenous environmental sources, and transmission by healthcare personnel. Pneumonia, central venous lines, and burn wounds are the most common sources of bloodstream infections, which typically occur within a week of injury.

Preventative measures against infection are critical for the burn injury patient and include early excision of burn eschar to improve local perfusion and prevent microbial colonization, prudent use of invasive devices, application of antimicrobial burn dressings, and diligent compliance with infection control practices. To avoid selection of resistant pathogens, prophylactic systemic antibiotics should not be administered.[189] For patients with documented infection, antibiotics should be culture-directed. Knowing incidence and sensitivities to unit specific pathogens will allow more accurate targeting of empirically prescribed antimicrobials. Dosing should be adjusted to account for the altered organ function. Regular monitoring of antibiotic levels is important as evidence suggests that many patients never achieve the recommended therapeutic antibiotic concentrations.

Topical antimicrobials consist of a wide range of agents targeted at reducing the incidence of wound infection by controlling microbial contamination at the wound surface. An advantage of local antimicrobial therapy is the ability to get high concentrations of the active agent at the site. Systemic agents are less successful in treating local infections because they most often do not reach the burn wounds in large concentrations because of the microthrombosis of vessels and wound edema. Eschar penetration, safety profile, desired spectrum of activity, patient tolerance, and projected length of therapy must be balanced.[190] Silver nitrate, silver sulfadiazine, and silver-based dressings are the most commonly used agents. Silver works quickly and may have one of the broadest spectra of activity that includes gram-positive, gram-negative, and fungal organisms. Mafenide is an alternative topical agent that offers the added benefit of eschar penetration for deep burns. Although rare, adverse reactions from mafenide can occur in sulfa-allergic patients and metabolic acidosis from carbonic anhydrase inhibition has been reported.[191]

Early recognition and treatment of sepsis may reduce the incidence of complications and improve survival. Identifying sepsis can be challenging in light of the hyperdynamic, hypermetabolic, and proinflammatory response to burn injury. Systemic inflammatory response syndrome criteria have poor correlation with infection in burn injury patients, with more than 90% of patients fulfilling criteria regardless of clinical stability or infection status.[192,193] Standardized criteria for diagnosis of sepsis and infection-related diagnoses were developed more than a decade ago for burn injury patients.[194] These burn-specific criteria for sepsis include (three of the following with documented infection): temperature over 39°C or under 36.5°C, tachycardia greater than 110 beats/min or more than 2 standard deviations from value for age, progressive tachypnea (spontaneous ventilation: respiratory rate >25 or as necessary for mechanical ventilation), hyperglycemia (plasma glucose ≥230 mg/mL) in the absence of diabetes mellitus, thrombocytopenia (will not apply until 3 days after initial resuscitation; platelet count ≤100,000 μ/L), and the inability to continue enteral feeding for more than 24 hours. Other clinical indicators of sepsis may include increased fluid requirements, hypotension, altered mental status, and worsening renal status. It is likely that use of multiple indicators of sepsis will improve the sensitivity and specificity of early sepsis diagnosis in this clinically more difficult setting.[195]

Burn wounds are particularly known to be tetanus prone. Patients who are current with vaccination status require no further treatment while those with unknown or inadequate vaccination status should receive tetanus toxoid in addition to tetanus immune globulin.[196,197]

Metabolic Considerations

The hypermetabolic response after burn injury is more severe and sustained than any other form of trauma. Burn injury patients have increased resting energy expenditures, increased myocardial oxygen consumption, marked tachycardia, increased body temperature, glycolysis, proteolysis, lipolysis, and futile substrate cycling.[198] Marked and sustained increases in catecholamine, glucocorticoid, glucagon, and dopamine secretions are thought to initiate the cascade of events leading to the acute hypermetabolic response with its ensuing catabolic state. The role of DAMPS in this hypercatabolic state has not been elucidated.[199] The metabolic rate of patients with greater than 40% TBSA burn can exceed 180% of non-burned levels during admission and 150% at the time of complete wound healing.[200] Furthermore, the hypermetabolic response to burn injury persists well beyond wound closure, with metabolic and inflammatory changes that can occur up to 3 years after the injury, especially in children with very large burns.[201] This high metabolic demand and energy expenditure results in the catabolism of lean muscle mass, which may have important detrimental effects for the complete recovery processes.[198]

The relevance of the postburn hypermetabolic and inflammatory effects includes prolonged insulin resistance, increased fracture risk, increased liver size due to steatosis, growth impairment, increased cardiac work and dysfunction, protein catabolic state, and impaired muscle strength, hormonal abnormalities, and increased risk for infection. Consequently, severe burn injury is not an acute illness but rather a chronic health problem. Numerous strategies have been employed to modify this catastrophic response including early excision and grafting, thermoregulation, and early aggressive enteral feeding. There are several proven pharmacologic approaches to attenuate the hypermetabolic flow phase of a burn. Adrenoceptor blockade (most commonly with the nonselective β-blocker, propranolol) has favorable effects on heart rate, resting energy expenditure, oxygen consumption, and net muscle-protein balance.[203] Insulin therapy promotes maintenance of muscle mass and improved donor site healing, without increasing hepatic triglyceride synthesis. It also attenuates the inflammatory response.[204-206] Oxandrolone, a synthetic androgen, has been shown to increase both muscle protein synthesis and muscle strength as well as improve bone mineral content, and is today recommended in burn care guidelines.[207] Despite these pharmacologic therapies, muscle wasting of burn injury persists for several years. More research is needed to better manage these functional deficits.

Nutrition

Nutrition is of critical importance for the burn injury patient. It has been estimated that a patient’s basal energy needs may benefit up to 200%.[208] Nutritional support not only partially abates the hypermetabolic response and attenuates muscle protein loss but also modulates stress hormone levels, improves gut mucosal integrity, improves wound healing, and decreases the risk of stress ulcer formation. Growing evidence suggests that early nutrition is safe, efficacious, and leads to better outcomes. In addition, evidence suggests that delay in enteral nutrition leads to a higher incidence of gut mucosal atrophy, microbial translocation, which can lead to sepsis, and multiorgan failure. The potential disadvantage of early feeding is a higher risk of complications when the patient is being resuscitated from burn shock. Gastric ileus is not uncommon in the early phase, and feeding could lead to a higher risk of aspiration. In addition, there is a concern that burn injury patients who are still in shock may be at risk of intestinal necrosis if fed.

Enteral nutritional support should be used in preference to parenteral nutritional support. Parenteral nutrition should be reserved for those with prolonged ileus and or enteral feeding intolerance. Oral feeding is preferred to enteral feeding (liquid formulae given through nasoenteric tubes) because of the reduction in both cost and complications. However, the severely injured are unable to eat enough to satisfy the hypermetabolic response. While underfeeding can result in complications, it is important to recognize that overzealous nutritional support offers little additional benefit and may be harmful. Overfeeding can result in fluid and electrolyte imbalances, hyperglycemia, and hepatic steatosis. Although formulae exist to predict total caloric requirements, these often lead to underfeeding during periods of highest energy utilization and to overfeeding late in the treatment course. As there is also a large interindividual variability, actual caloric requirements should be determined by measuring resting energy expenditure with indirect calorimetry.[209]

Patients who suffer from extensive burn injury will often undergo multiple operative procedures often under general anesthesia. Historically, the use of general anesthesia requires patient’s to be nil per os (nothing by mouth, NPO) at midnight of the intended procedure day. This practice can lead to a major void in a burn patient’s caloric support. The feasibility and safety of continuing enteral feeding throughout operative procedures has been studied.[210] Enteral feeding using post-pyloric tubes has been successful, provided the airway was secured via a cuffed ETT or tracheostomy (to prevent aspiration of gastric contents).[211,212] Nevertheless, it is prudent to hold enteral feedings when there is potential for increasing abdominal pressure (e.g., prone position or surgery on the abdomen) or when an airway procedure such as tracheostomy is to be performed.

Anesthetic Management

PREOPERATIVE EVALUATION

Patients are often brought to the operating room in the early phase of burn injury, when they are undergoing significant

BOX 87.3 Major Perioperative Concerns for the Burn Patient

- Age of patient
- Extent of burn injury (total body surface area, depth, and location)
- Mechanism of injury
- Elapsed time from injury
- Associated injuries
- Inhalational injury and/or lung dysfunction
- Adequacy of resuscitation
- Coexisting diseases
- Airway patency
- Difficult vascular access
- Gastric stasis
- Altered drug responses
- Altered mental states
- Pain/anxiety
- Presence of organ dysfunction
- Presence of infection
- Susceptibility to infection
- Hematologic issues (anemia, coagulopathy)
- Magnitude of surgical procedure

fluid shifts with corresponding cardiovascular instability and/or respiratory insufficiency. Early excision of dead/necrotic tissue with temporary or permanent coverage of the open areas is important for decreasing the burden of wound colonization and systemic sepsis. In addition to standard preoperative evaluation, there are specific features of the history and physical examinations, which deserve additional focus in the burn injury patient. These include the time and extent of burn injury, airway evaluation, presence of inhalation injury, quantity of fluid received, current resuscitation regimen and the patient's response, vascular access/sites, and tolerance of enteral feeding and NPO status (Box 87.3). Communication with the surgeons and the critical care team is crucial to manage perioperative care in a manner that is compatible with treatment goals of the intensive care unit (ICU). Details of the surgical plan, including the extent and anticipated duration of the procedure, are also essential to estimate blood loss and to plan appropriate vascular access, invasive monitors, arrange thermoregulation, and to order appropriate blood products. Conferring with the nurse taking care of the patient will provide valuable information about the current status of the patient.

Intraoperative Management

AIRWAY MANAGEMENT

Airway management in the burn injury patient may be challenging and warrants particular consideration (see Fig. 87.2). Key features of airway assessment include preexisting airway abnormality, current airway injury (i.e., inhalation injury), and signs of glottic obstruction. The type of airway abnormalities may vary depending on the stage of the injury. In the acute burn setting, mandibular mobility and mouth opening may be limited because of edema or, in later care, the developing contractures. Preanesthetic assessment of the patency and soft-tissue compliance of the airway are essential. Palpation of the neck and submandibular space may reveal tightness that will limit displacement of the tongue and soft tissues into the submandibular area, making laryngoscopy challenging. Dressings and nasogastric tubes may make face mask seal difficult. Facial wounds may be painful, and exudate and topical antibiotics may result in a slippery skin surface and difficulty holding the mask. Burn victims, who are beyond the acute phase of injury, may have significant scarring and contractures in the face, mouth, nares, neck, and chest, which can make airway management very difficult.[213,214] The airway sequelae of burn and inhalation injury or tracheostomy can also include subglottic stenosis, tracheomalacia, granuloma formation, obstruction of the nares, and fixation of the neck in a flexed position. If a patient is suspected to be difficult to mask ventilate, it is wise to either confirm the ability to mask ventilate prior to giving drugs that promote apnea or maintain spontaneous ventilation throughout the induction and intubation. The utility of traditional adjuncts used to facilitate mask ventilation, such as an oral airway, nasal airway, jaw thrust, chin-lift, and two-hand mask ventilation, may be limited in the burn injury patient. An oral airway may be difficult to insert in patients with microstomia, as would a nasal airway in patients with scarring of the nares. Chin-lift and jaw-thrust may be impossible because of scarring and contractures, which can limit neck extension and anterior displacement of the mandible.

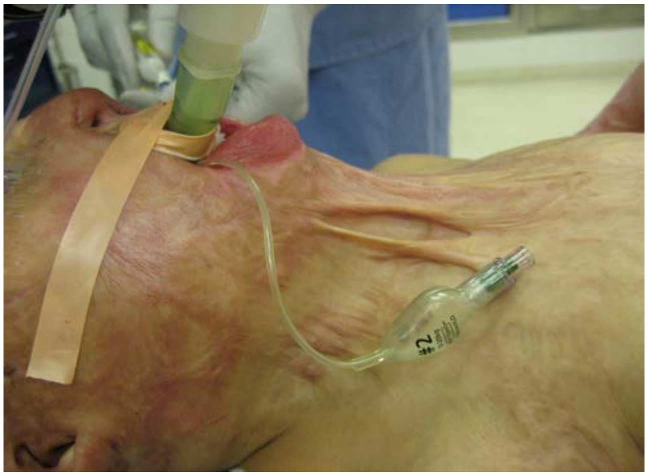

Fig. 87.3 Burn-injured patient with a severe neck contracture undergoing general anesthesia with a laryngeal mask airway.

The laryngeal mask airway (LMA), a supraglottic airway device, has been successfully used as both an alternative to tracheal intubation and a rescue airway device for burn injury patients (Fig. 87.3).[215] Use of the LMA for airway management may help avoid further laryngeal injury associated with tracheal intubation. It can also serve as an aid to fiberoptic intubation. However, microstomia and fixed neck flexion from contractures can limit its use. Microstomia can impair the ability to insert the LMA into the oropharynx. Fixed neck flexion makes insertion difficult because the distal end of the LMA abuts the chest wall. Surgical release of neck contractures under local anesthesia prior to intubation may be required in severe cases.

If the preoperative examination reveals concern for upper airway patency, mobility, or mask ventilation, fiberoptic

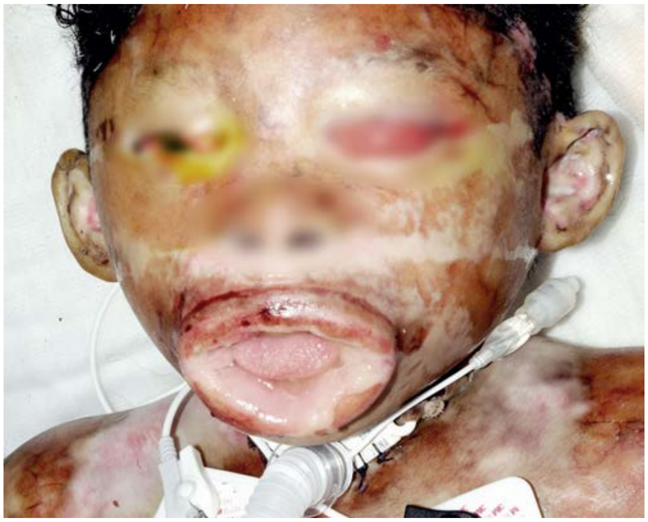

Fig. 87.4 Pediatric patient with burns of the face and neck. The patient underwent early tracheostomy due to profound swelling of the airway present.

intubation while maintaining spontaneous ventilation should be considered. If the patient is uncooperative, inhalational induction or the use of ketamine preserving spontaneous ventilation may permit the advancement of the fiberoptic scope. It is important to avoid gag and laryngospasm during the fiberoptic intubation. Traditional methods to topicalize the airway to prevent gag include using preinduction nebulized lidocaine or lidocaine gargle and postinduction lidocaine sprayed directly on the vocal cords via the fiberscope. Video laryngoscopy is an alternative intubating tool that also permits assessment of hypopharyngeal and glottic anatomy. In children awake intubation is not a viable option. Ketamine-induced sedation/anesthesia maintains the pharyngeal muscle tone and can be used for fiberoptic intubation in children. Tracheostomy completely done under local anesthesia is also at times a viable option (Fig. 87.4). A surgeon capable of performing a potentially difficult tracheostomy should be readily available when there is any question of inability to manage a patient with an anticipated difficult airway. The distorted anatomy can make a surgical tracheostomy difficult in both elective and urgent situations.

Gastric emptying may or may not be delayed in burn injury patients.[216] Sepsis, intestinal edema, and opioids may slow gastric emptying, with increased risk of aspiration. If there is concern for ileus, rapid sequence induction is generally required. The use of the LMA in the presence of decreased chest or abdominal compliance can result in redirection of ventilated volume from the lungs to the stomach. Regurgitation of gastric contents can occur in these instances significantly complicating the procedure.

It is essential to secure the ETT to avoid unintentional extubation. Traditional securing methods using adhesive tapes or ties are unsuitable in patients with facial burns since tape or ties crossing burned areas can irritate the wound or cause injury to grafts. Placement of a circumferential tie around the patient's head, using wire to secure the tube to a tooth, or use of arch bars can provide safe fixation.[217-220]

The use of cuffed ETTs in the pediatric burn population, both in the operating room and in the ICU, is safe and recommended regardless of the child's age.[221] Considerable fluctuation in airway diameter can occur throughout the patient's acute hospital course because of laryngeal, tracheal, and bronchial edema. With fluctuations in airway diameter, the ETT cuff may need to be readjusted to facilitate mechanical ventilation without a leak or prevent overpressure in the cuff, which can cause tracheomalacia.

Severely burn-injured patients may require tracheostomies because of potential complications from long-term translaryngeal intubation for mechanical ventilation. The optimal timing and indications for tracheostomy remain unresolved.[222] In general, early tracheostomy should be considered if prolonged mechanical ventilation is anticipated (inhalation injury, advanced age, chronic pulmonary disease, other significant systemic comorbidities, and large burn size). Complications can occur, particularly when tracheostomies are performed under nonelective conditions, through burned tissue or in the presence of edema. Tracheostomy-related dysphagia, dysphonia, and other laryngeal pathologies have been described in burn injury patients.[223]

VASCULAR ACCESS

Vascular access in burn injury patients can be challenging. The anatomy of typical vascular access sites can be distorted by the burn injury and in the setting of acute injury, patients can be hypovolemic, making venous access technically difficult to obtain. In addition, resuscitation can result in edema. In pediatric patients, the task can be even more difficult. It may be necessary to place vascular catheters through burn-injured tissue or wounds. On occasion, it may be necessary to have the surgeons debride the insertion site just before placement of the vascular catheter. If no intravenous access is available, temporary intraosseous cannulation may safely be placed in patients of any age. This technique obviates the need for venous cutdowns and can be useful in emergency situations. A multiport central venous catheter is usually necessary in patients with large burn injuries because of incompatibility of resuscitation fluids with drugs, blood, and the need for hyperalimentation. Localization of vessels using ultrasonographic guidance can be useful in placing peripheral and central catheters in patients when access is difficult.[224]

Because burn injury patients undergo multiple surgical procedures during their hospitalization, access is required multiple times. Central venous catheters can be kept in place without changing them for more than 7 to 14 days, provided extreme aseptic techniques are practiced during their insertion and use. When a new catheter is needed, the insertion can be rotated and include the jugular, subclavian, and femoral veins. For excision and grafting procedures, securing adequate vascular access before the surgical procedure begins is necessary as blood loss can be rapid and substantial.

VENTILATOR MANAGEMENT

Respiratory failure is common after serious burns caused by inhalation injury, due to inflammatory mediators from the burn, effects of fluid resuscitation, and infection. In providing intraoperative mechanical ventilation, the same considerations used in the ICU must be followed to avoid barotrauma. Although the concept has not been tested in this population, growing evidence supports the importance of maintaining lung protective ventilation even in the operating room. During the hypermetabolic state (beginning ~48-72 hours after burn injury), oxygen consumption and carbon dioxide production can be significantly increased. Consequently, minute ventilation can exceed 20 L/min in an adult patient with a large burn.

Extensive excision and grafting procedures may result in such a physiological disturbance that postoperative mechanical ventilation is needed. The reabsorption of tumescent fluid used during surgery and the surgery-induced bacterial and cytokine release can aggravate the lung dysfunction. The decision to wean from mechanical ventilation and extubate after surgery is based on the same considerations as in the nonburn patient. Extubation should not be performed in the presence of hemodynamic instability, significant metabolic derangement, hypothermia, sepsis, or worsening pulmonary function. Assessment of extubation readiness should include assessment for edema in the upper airway and glottis. The presence of a good air leak after deflation of the endotracheal cuff is an indirect estimate of an adequate glottic opening. Direct visualization using direct laryngoscopy or with flexible FOB is often performed in the operating room prior to planned weaning and extubation.

MONITORING

As with any patient suffering from multiorgan dysfunction, intraoperative monitoring of the burn injury patient depends on the patient's physiologic status and extent of planned surgery. The injury per se can make placement of these monitors challenging when standard sites are burned or are within the surgical field. Difficulty may be encountered in adherence of standard electrocardiogram (ECG) electrodes as a result of exudation of fluid from the injured sites or the presence of topical antibiotic ointment. Use of needle electrodes or surgical staples to fix the electrodes can be effective. Alternatively, placing the electrodes on the back or dependent sites may hold them in place. Application of pulse oximetry probes can also be difficult and may require alternative sites, such as the ear, nose, or tongue in such circumstances. In an extensively burned patient, a blood pressure cuff may have to be placed directly over injured or recently grafted tissue. In this circumstance, great care should be taken to protect the underlying area and a sterile cuff should be used. If rapid or extensive bleeding is expected, an arterial line should be considered for continuous measurement of blood pressure and blood sampling. In addition, the arterial pressure waveform and its alterations in relation to respiration provide continuous hemodynamic information about fluid responsiveness and cardiac output and can be used to guide volume and vasoactive therapy.[225] Temperature monitoring is imperative as these patients are susceptible to and intolerant of hypothermia. Monitoring of body temperature is also useful for detection of blood transfusion reactions intraoperatively (>2°C rise in temperature). Neuromuscular function monitoring in patients receiving neuromuscular blocking drugs is required as dose requirements can be significantly altered. However, continuous use of muscle relaxants during burn surgery is seldom needed. Multiport central venous catheters are useful for simultaneous monitoring of central pressures and administering of drugs and fluids. Meticulous care to prevent contamination from exogenous sources of all existing or planned introduction of catheters and tubes should always be observed.

PHARMACOLOGIC CONSIDERATIONS

Burn injury causes pathophysiologic changes in the cardiovascular, pulmonary, renal, and hepatic systems, as well as in concentrations of circulating plasma proteins as a result of the release of endogenous mediators, and hormones together with exogenous ligands that are administered affect receptor plasticity. These changes result in altered pharmacokinetic and pharmacodynamic responses to many drugs, and these responses may vary depending on the burn severity and the time elapsed after the injury.[226,227]

The two distinct phases of cardiovascular and metabolic responses to burn injury can affect pharmacokinetics in different ways. During the acute injury phase (0-48 hours), there is rapid loss of fluid from the intravascular space, resulting in decreased cardiac output and blood flow to organs and tissues. Despite adequate resuscitation, patients may continue to have decreased cardiac output and decreased renal and hepatic blood flow. During this phase, there will be decreased elimination of some drugs by the kidney and liver. Because of decreased intestinal blood flow, absorption of oral drugs will also be delayed. Following the resuscitation phase, the hyperdynamic phase begins, which is characterized by increased cardiac output and increased blood flow to the kidneys and liver. Drugs dependent on organ blood flow will have increased clearances; drug doses may have to be adjusted upward accordingly.

The two major drug-binding proteins, albumin and α1-acid glycoprotein (AAG), are altered in opposite ways after burn injury.[227] The concentration of albumin, which binds to mostly acidic and neutral drugs, is decreased in burn injury patients while AAG, which binds cationic drugs, is an acute-phase reactant and its concentration increases twofold or greater in these patients.[229] Cationic drugs (lidocaine, propranolol, muscle relaxants, and some opioids) bind to AAG, resulting in decreases in free fraction. Most likely related to the decreased albumin levels and continued fluid leak through burn wounds and/or resuscitation fluids, there is an increase in volume of distribution of almost every drug studied (propofol, fentanyl, muscle relaxants). In addition, pharmacodynamic changes at target organs alter drug-receptor interactions causing variable and at times unpredictable changes in responses to drugs. Consequently, changes in the usual dosages of drugs or complete exclusion of other drugs (e.g., succinylcholine) may be *necessary* to ensure efficacy, patient safety, or avoid toxicity.

Clearance of drugs highly extracted by the liver depends primarily on hepatic blood flow and is relatively insensitive to alterations in protein binding. Thus clearance of highly extracted drugs (e.g., propofol, fentanyl) may decrease during the early postburn phase as a result of hypoperfusion from hypovolemia and hypotension, and subsequently increase during the hyperdynamic phase when hepatic blood flow increases.[230,231] During the hypermetabolic phase, renal blood flow and glomerular filtration rate increase. Thus renal clearance of some drugs (antibiotics [gentamicin, cephalosporins] and H_2-receptor antagonists [ranitidine]) will have enhanced elimination.[232,233] In contrast, clearance of drugs that have a low hepatic extraction coefficient is unaffected by changes in hepatic blood flow, but is sensitive to alterations in plasma protein levels as it is the unbound fraction of drug that is metabolized. Hepatic enzyme activity also appears to be altered in patients with burns.[226] Phase I reactions, which include oxidation, reduction, hydroxylation, and demethylation, are impaired after burn injury (e.g., diazepam). Phase II reactions involving conjugation, glucuronidation, and sulfation seem to be relatively unaffected (e.g., lorazepam).[235] Additionally, systemically administered drugs may leak out through the burn wound, and blood loss during surgery can potentially exaggerate the elimination of drugs.

ANESTHETIC DRUGS

Many inhalation and intravenous drugs have been used successfully for the induction and maintenance of anesthesia in burn injury patients.[230] Choice of drug should be based on the patient's hemodynamic and pulmonary status and the potential difficulty in securing the patient's airway. Because of its rapid onset and lack of pungency, sevoflurane offers advantages for smooth inhalation induction in children or adults with abnormal airways or those without intravenous lines. The choice of volatile aesthetic does not appear to influence outcome in these patients. Long-term sequelae of repetitive anesthetics in pediatric patients is unknown.

Propofol clearance and volume of distribution are increased in patients with major burns during the hyperdynamic phase of injury.[230] Therefore in comparison with nonburned patients, those with major burn injury may require larger bolus doses and/or increased infusion rates of propofol to attain or maintain therapeutic plasma drug concentrations. Attention to the hemodynamic consequences of administering larger doses of propofol is warranted.

Opioids

Opioids are the mainstay of analgesia in this population of patients because (1) they are potent, (2) the benefits and risks of their use are familiar to the majority of care providers, and (3) they provide a dose-dependent sedation that is beneficial during painful and anxiety-provoking wound-care procedures.[238] The wide spectrum of opioids available for clinical use provides dosing flexibility (i.e., variable routes of administration, time until effect, and duration of analgesia), which can target different pain qualities and contexts. For example, oral opioids with delayed systemic uptake (e.g., sustained-release morphine, fentanyl patch) or prolonged terminal half-life (e.g., methadone) are effective in treating background pain. In contrast, short-acting agents with rapid onset (e.g., intravenous fentanyl, alfentanil) are better suited for procedural pain alleviation. During the acute phase of injury, potent opioids such as morphine sulfate, hydromorphone, and fentanyl should be given intravenously and titrated based on patient response. It is not clear that the use of any one opioid offers fewer side effects than another.

Many patients are receiving continuous infusions of opiates and sedatives before surgery. These infusions have been maintained to reach a steady state of effect and should not be stopped. Intraoperative analgesia can be achieved by increasing these infusions or turning to other drugs. Fentanyl is commonly used as an analgesic in the operating room as well as for sedation in burn care units. The volume of distribution and clearance of fentanyl are increased following burn injury partly explaining the increased dose requirement of this drug.[239,240] A decreased volume of distribution and clearance of morphine has been reported in burn patients, with an expected increase in elimination half-life.[241] However, other literature has suggested no significant difference in morphine pharmacokinetics between adults with and without burn injury.[242]

Patient-controlled analgesia (PCA) with intravenous opioids has been shown to be a safe and effective method of opioid delivery for acute or procedure-related pain in both children and adults with burn injury.[243-246] PCA also provides benefit by allowing the patient to retain some degree of control over his/her medical care (i.e., control coping).

The analgesic efficacy of opioids decreases with time resulting in the need for increasing dosage requirements to achieve an equivalent effect. Opioid tolerance, a diminished opioid anti-nociceptive effect following repeated exposure to opioid, may be apparent as early as after 1 week of uninterrupted opioid use.[175] It is not uncommon for these patients to manifest opioid tolerance requiring dosage amounts that far exceed standard textbook recommendations.[248] Studies with burned animals have suggested intrinsic pharmacodynamic opioid receptor alterations. These include desensitization and downregulation in μ-opioid receptors, and upregulation of protein kinase C-γ and *N*-methyl-D-aspartate (NMDA) receptors.[249] In view of the NDMA upregulation following burns, it is not surprising that ketamine requirements to anesthetize patients also are increased following burn injury.[250] Adverse effects of opioids, such as respiratory depression, acute opioid tolerance, and hyperalgesia, particularly with the need for rapidly escalating doses, have generated increasing attention to multimodal strategies. Clonidine, dexmedetomidine, ketamine, and methadone have been found to be effective in the treatment of pain in patients with extreme tolerance to morphine.[251,252]

A variety of non-opioid analgesics are useful for treating burn pain since their benefit and side effect profiles differ from opioid analgesics (Table 87.2).

NSAIDS

Acetaminophen and nonsteroidal antiinflammatory drugs (NSAIDs) are useful first-line analgesics for minor burns.[253] However, NSAIDs and acetaminophen exhibit a ceiling effect in their dose-response relationship, rendering them inadequate as a single agent for the treatment of severe burn pain. NSAIDs can also have deleterious effects including bleeding risk, gastrointestinal, cardiovascular, and renal complications. As a consequence, NSAIDs are generally avoided in patients with major burns.

α2 Agonists

Clonidine or dexmedetomidine (α2-adrenoceptor agonists) can be useful analgesic adjuncts without causing respiratory depression.[254] However, the α2-adrenoceptor agonists can cause hypotension in higher doses and in the presence of hypovolemia; therefore these should not be

TABLE 87.2 Sedation and Analgesia Treatment Guideline

Stage of Injury	Background Anxiety	Background Pain	Procedural Anxiety	Procedural Pain
Acute burn mechanically ventilated	Midazolam infusion or Dexmedetomidine infusion Antipsychotics Propofol infusion	Morphine infusion	Midazolam bolus Dexmedetomidine at higher infusion rates Antipsychotics Propofol boluses	Morphine bolus Ketamine IV
Acute burn not mechanically ventilated	Scheduled lorazepam PO or IV or Dexmedetomidine	Scheduled morphine PO or IV	Lorazepam PO or IV	Morphine PO or IV
Chronic acute burn	Scheduled lorazepam or antipsychotics (PO)	Scheduled morphine or methadone	Lorazepam or antipsychotics (PO)	Morphine PO or oxycodone

IV, Intravenous; *PO,* per os (orally).

given to hemodynamically unstable patients. Dexmedetomidine has been used to provide sedation–analgesia for burned patients and to decrease opioid requirements.[255] However, α2 agonists have also been reported to increase excitability of heat-sensitive cutaneous nociceptors but the clinical relevance of this finding in burn patients remains unclear.[256] The use of dexmedetomidine has recently been reported to reduce the risk of developing delirium when used for ICU sedation, especially in comparison to benzodiazepines.[257]

Anxiolytics

The recognition that anxiety can exacerbate acute pain has led to increased use of anxiolytic drugs in combination with opioid analgesics. The combination of benzodiazepines and opioids is particularly useful in premedicating patients for wound care to help reduce the anticipatory anxiety related to such procedures. Patients most likely to benefit from this combined treatment are those with either high anxiety at the time of the procedure or high baseline pain scores.[258] The tolerance to opiates seems to be exaggerated by long-term administration of the benzodiazepine, midazolam.[259]

Gabapentin

Gabapentin is an anticonvulsant that has increasingly been used for chronic and neuropathic pain, and as an adjunct pain medication that may play a role in modulating central sensitization and hyperalgesia. Several studies have shown gabapentin to be a beneficial addition to an opioid analgesic regimen in this population.[260,261]

Ketamine

Ketamine is a dissociative anesthetic that induces rapid and profound sedation, analgesia, and amnesia. It causes functional dissociation between the limbic and the cortical systems, producing a trance-like cataleptic state that impairs sensory recognition of painful stimuli and memory. In addition, by acting as a noncompetitive NMDA receptor antagonist, it is thought to both prevent the induction of central pain sensitization and its windup, thereby reducing the development and maintenance of opioid tolerance and hyperalgesia. Ketamine is a widely used analgesic agent in all stages of burn injury, both primarily and as an adjunct to other analgesic regimens.[262] Intravenous ketamine is commonly used for procedures requiring deep sedation such as dressing changes and line placement because of its rapid onset and short duration of action, which is due to rapid redistribution. Intravenous ketamine infusions can be continued safely in the ward environment after discharge from ICU. Ketamine can also be used for long-term administration although tolerance develops with time. The other advantage is that it can be weaned rapidly without adverse consequences even after long-term use.[263]

Ketamine has many potential advantages for induction and maintenance of anesthesia in burn patients.[264] Ketamine is associated with hemodynamic stability, preservation of hypoxic and hypercapnic responses, and decreasing airway resistance. Ketamine may exert beneficial antiinflammatory effects in patients with burns and or sepsis. Also, by causing peripheral vasoconstriction, ketamine may be advantageous for patients at risk for hypothermia.[265] Whether peripheral vasoconstriction occurs in patients with major burns, and whether this causes a reduction in blood loss, is unknown. It is important that bolus doses of ketamine can cause hypotension in some patients with burn injury, despite ketamine-induced catecholamine release. This occurs because of the persistently high levels of catecholamines in these patients that result in desensitization and downregulation of β-adrenoreceptors.[266] As a result, direct myocardial depressant effects of ketamine can manifest.

Another important feature of ketamine is that, unlike all other anesthetic agents, muscle tone and protective airway reflexes are preserved. Consequently, ketamine may be the agent of choice if one wishes to avoid manipulation of the airway (e.g., after placement of fresh facial grafts, for stent or dressing removal, for brief procedures such as dressing or line changes, or for patients with TENS).

Ketamine administration can result in a number of side effects including nausea and vomiting, hallucinations, mood alteration, bizarre dreams, and emergence delirium, which tend to occur when ketamine is used as a single agent, when given in large doses, and if administered rapidly. The administration of a benzodiazepine in combination with ketamine has been shown to decrease the frequency and severity of emergence reactions.[267]

Regional Anesthesia

Regional anesthesia can be advantageous in targeting specific aspects of burn-injury pain. In its simplest form, regional anesthesia may be tumescent local anesthesia injected into a donor site prior to harvesting or it can take the form of subcutaneous catheter infusions, peripheral nerve blocks, or central neuraxial blockade.[268–271] While regional anesthesia can be the primary anesthetic management for surgical burn care, it is frequently also utilized as an analgesic adjunct, enabling opioid sparing and improved postoperative analgesia. Placement must take into consideration that skin donor sites and injury sites are often in different anatomic locations and that patients often have more intense postoperative pain from the split-thickness skin donor site than from the grafted burn wound.

Central neuroaxial techniques (spinals, epidurals) have been used with good effect as both primary anesthetics and postoperative adjuncts.[272-274] However, fear of meningeal spread in patients densely colonized with infectious organisms, reluctance to inserting a needle through burned tissue, and anatomic surgical incompatibilities (e.g., the need to graft lower extremities but donor sites are on upper extremities or trunk) may limit their use. There are no reports suggesting epidural abscesses are more common in burn patients, but reports have suggested that intravascular catheters are more likely to become infected if placed in or near burned tissue.[275] Administration of local anesthetics (and/or opioids) via an epidural catheter would seem to be of benefit in patients with lower extremity burns, resulting in both background and procedural analgesia, as well as autonomic sympathectomy and peripheral vasodilation.

Truncal blocks (paravertebral and transversus abdominis plane [TAP] can be very useful to provide analgesia for donor-site harvesting, and both block techniques are also amenable to placement of catheters to extend duration of postoperative analgesia.[276] As for central neuraxial catheters, there are theoretical concerns of increased infection with placement of a foreign body (i.e., catheter) in these patients, but such infections have not been reported. It is also likely that infection from a paravertebral or TAP catheter would be a less catastrophic event than an infection from a central neuraxial catheter (e.g., epidural abscess).

The lateral femoral cutaneous nerve is particularly well suited to block because it is exclusively a sensory nerve and innervates an area (the lateral thigh) that is frequently chosen for split-thickness skin grafts.[277,278] Sometimes there is a need to cover the anterior and medial thigh due to the extent of skin harvest, and therefore a fascia iliaca block can also be performed.

The pharmacology of local anesthetics in burn injury patients may be altered by changes in hepatic function, protein binding, and volumes of distribution.[279] The incidence of adverse effects of local anesthetics or tolerance does not appear altered in the burn patient, per se, but caution is advised in the use of these potentially neuro/cardiotoxic agents in critically ill burn patients. Recent advances in local anesthetics, such as liposomally enclosed lidocaine and bupivacaine, have the potential to offer longer duration of action with greater safety (i.e., local anesthetics stay *locally*), but studies specific to burn patients have yet to be performed.[280]

Muscle Relaxants

Muscle relaxant pharmacology is significantly and consistently altered after burn injury.[281] Exposure to succinylcholine can result in an exaggerated hyperkalemic response, which can induce cardiac arrest. The current recommendation is to avoid succinylcholine administration in patients 48 to 72 hours after burn injury.[282,283] An increase in the number of extrajunctional acetylcholine receptors that release potassium during depolarization with succinylcholine is the cause for increased hyperkalemia. The duration of the hyperkalemic response most likely varies with the severity of the injury and accompanying critical illness, and the extent of muscle recovery. The presence of aggravating factors such as disuse (contractures), immobilization due to long-term bed rest, inadequate nourishment, and possibly ICU myopathy may also contribute to these changes and would likely make the potential of hyperkalemia more likely.[281] Almost paralleling the hyperkalemia to succinylcholine, there is concomitantly a decreased sensitivity to the neuromuscular effects of nondepolarizing muscle relaxants (NDMRs). Resistance to NDMRs has been reported in pediatric patients 463 days after burn injury, suggesting that the hyperkalemic response to succinylcholine could also persist for more than a year.[284] Although a hyperkalemic response to succinylcholine may be seen, whether lethal levels would be reached is unknown after such a long period. Whether small doses (0.1 mg/kg) of succinylcholine, as might be used for treatment of laryngospasm, would result in less hyperkalemia has been inadequately studied.[285]

NDMRs are the relaxants of choice in burn patients. However, the dose and duration of onset required to achieve effective paralysis can be substantially increased while the duration of paralysis is reduced. The etiology of the altered response to NDMRs is multifactorial: (1) upregulation of acetylcholine receptors, including upregulation of fetal and α7 (neuronal type) acetylcholine receptors at the muscle membrane; and (2) increased binding to AAG and, enhanced adrenal and hepatic elimination of the NDMRs.[286,287] Resistance to the effects of NDMR is highly correlated with the magnitude of the burn and time after burn.[288]

Rocuronium is the drug of choice in burn patients when rapid onset of paralysis is necessary and succinylcholine is contraindicated. An increased rocuronium dose of 1.2 to 1.5 mg/kg for rapid sequence induction has been recommended in patients with major burn injury.[289,290] It must be noted, however, that even with a dose of 1.5 mg/kg of rocuronium, the onset time to effective paralysis approximates 90 seconds in burned patients compared with less than 60 seconds in nonburned patients with a dose of 0.9 mg/kg (Fig. 87.5). Even at the higher doses, the duration of action of rocuronium can be quite variable; therefore monitoring of neuromuscular function is essential to specifically determine the dose requirement and the adequacy of reversal in patients with major burns. Preliminary evidence suggests that sugammadex, a modified cyclodextrin used for reversal of rocuronium- and vecuronium-induced nondepolarizing muscle block, can be used in burn patients, with recovery times for muscle activity similar to that in other types of patients.[291]

Atracurium, broken down by organ-independent pathways (e.g., Hofmann elimination), also exhibits reduced neuromuscular effect following burns.[292] This suggests that the major component to resistance to NDMRs is pharmacodynamic in nature. No research study has specifically addressed the effect of cisatracurium following burn injury. However, it

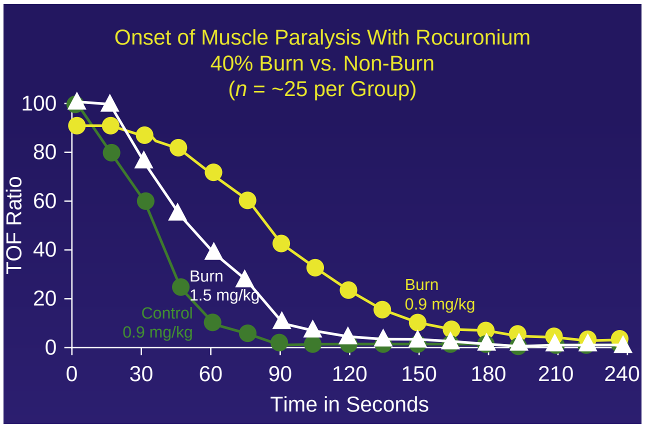

Fig. 87.5 Dose-response curves and time to maximal effect of rocuronium in adult burned and non-burned patients. Dose versus time to percent twitch suppression for rocuronium in control subjects and burned subjects of mean 40% total body surface area (TBSA) burn and studied at least 1 week after burn. In unburned patients the rocuronium dose of 0.9 mg/kg caused 95% twitch suppression in ≤60 seconds. The same dose has an onset of >120 seconds following major burn. Increasing doses of rocuronium shifted dose-response curves to the left. However, even with 1.5 mg/kg dose, the onset was still >90 seconds. TOF ratio refers to train-of-four ratio recorded in muscle during 2 Hz nerve stimulation.

can be inferred that cisatracurium may, too, have an altered pharmacodynamic profile, and dosing should be adjusted accordingly. Pharmacologic reversal of neuromuscular blockade with acetylcholine esterase inhibitors (e.g., neostigmine) poses no special problems in patients with burn injury.[283] Recovery of neuromuscular blockade has been observed at serum concentrations that would cause 100% twitch depression in nonburned patients.

FLUID MANAGEMENT AND BLOOD LOSS DURING EXCISION

Intraoperative fluid administration must be carefully optimized so as not to under-resuscitate or over-resuscitate, both of which may lead to further complications in the postoperative period. Considerations for intraoperative fluid management include the magnitude of burn excision (large excisions incur more blood loss), the depth of burn (partial-thickness burn excisions involve more blood loss than full-thickness burn excisions or fascial excision), the specific hemostatic techniques used (e.g., topical or subcutaneous epinephrine), and the volume of tumescent fluid administered. Injection of tumescent fluid into the burn or donor site should be minimized in the very young as gradual absorption of the tumescent fluid several hours later can lead to pulmonary edema.[294]

Correction of intravascular volume before induction of anesthesia is essential. Good communication between the surgical and anesthesia teams and limiting the operative duration and extent of excision can prevent such problems. Blood should be readily available before extensive burn excision is initiated.

Surgical excision of burn wounds is often associated with substantial bleeding. The hyperdynamic circulation and the inflammation-induced hyperemia exaggerate the blood loss. Published estimates of the amount of blood loss during burn excision operations are in the range of 3.5% to 5% of the blood volume for every 1% TBSA excised.[295] It is not uncommon for the surgical team to remove eschar so rapidly that the patient becomes hypovolemic and hypotensive. Increased blood loss also occurs because diffuse bleeding is used as an endpoint for excision, informing the surgeon that the tissue is viable. It is difficult to estimate blood loss during burn excision because shed blood cannot be efficiently collected in a suction canister, sponges may be presoaked with hemostatic agents, and substantial bleeding can continue unobserved beneath bulky dressings. As with the initial resuscitation, there is no single physiologic endpoint to use for titrating fluid replacement. Clinical judgment remains a vital component, using markers of hypoxemia, perfusion (base deficit, serum lactate), erythrocyte mass, coagulation, and pulse or arterial waveform as key assessment tools. In clinical practice, serial hemoglobin measurement in euvolemic patients is commonly used to determine the need for intraoperative transfusion. Rather than focusing on a single transfusion trigger, blood component therapy should be reserved for patients with a demonstrated physiologic need. Anticipation of continued blood loss may indicate transfusion to prevent significant anemia rather than waiting to treat it when it occurs.

Recent experience with civilian and military trauma with massive bleeding has demonstrated that mortality is decreased with an earlier and more aggressive administration of fresh-frozen plasma.[296] Criteria for massive bleeding include loss of total blood volume in 24 hours, 4 units of packed erythrocytes transfused in an hour, or ongoing loss of more than 150 mL of blood per minute and are not unusual for patients with large burns during burn wound excision. Although clinical experience with burn patients undergoing fluid resuscitation is not exactly equivalent to hemorrhagic shock of nonburned trauma patients, it is logical to assume that more aggressive use of fresh-frozen plasma to prevent development of coagulopathy may also benefit the burn injury population who also experience massive hemorrhage. The use of platelet transfusion may also be indicated in situations with larger losses, but endpoints for such transfusions remain unclear. Targeted correction of coagulopathy using thromboelastometry may reduce transfusion requirements during surgical burn wound excision as it may indicate which blood product is needed.[297]

Surgical hemostasis should be maintained during the burn wound excision in order to limit complications, sustain hemodynamic stability, and limit the number of blood transfusions necessary. Increased transfusion requirement is associated with poorer outcomes. Several methods have been used to maintain hemostasis, including topical application or subcutaneous infiltration of the burn wound and donor sites with diluted epinephrine solutions, limb elevation and use of tourniquets for extremity surgery, use of compression dressings, and topically applied thrombin and fibrinogen. In addition, a brisk operative pace is beneficial.

TEMPERATURE MANAGEMENT

Patients with major burn injury have an impaired ability for thermoregulation and therefore require close monitoring of body temperature. The anesthetic-induced vasodilatation and surgical preparation with alcohol may aggravate the heat loss. The inflammatory response to large burns causes an increase in the hypothalamic core temperature set point and the metabolic rate is increased to maintain this increased temperature. Hypothermia is therefore poorly tolerated as it causes an exaggerated increase in oxygen consumption and exacerbates the catabolic response to the injuries. Consequences of hypothermia during burn excisions also include decreased cardiac output, arrhythmias, abolition of hypoxic pulmonary vasoconstriction, left shift of the hemoglobin dissociation curve, interference with the normal blood coagulation mechanisms, and reduction of hepatic and renal function, as well as the reduced effect of inotropes. Intraoperative hypothermia (<36.0°C) has been associated with significantly increased blood loss, wound infection, and acute lung injury during burn surgery.[298,299] Postoperative consequences of hypothermia include shivering, impairment of drug clearance, and masking of hypovolemia. Furthermore, shivering can dislodge grafts and increase oxygen consumption by up to 500%, resulting in increased demand on the cardiopulmonary system as well as altering nutritional needs.[300]

Maintaining body temperature in these patients is challenging. Multiple strategies are used to maintain body temperature in the operating room, including use of forced-air warming blankets, thermal water mattresses, blood/fluid warmers, minimizing skin surface exposure, and wrapping the head and extremities with plastic or thermal insulation.[298] From an efficacy perspective, water-based mattresses, which provide convection heating, have a significant advantage.[302] Temperature in the operating room is commonly maintained at 80°F to 100°F (27°C-38°C), depending on the age and severity of the burn. Although a hot operating room can be uncomfortable for the operating room staff, it is often essential for maintaining the patient's temperature. The ambient temperature of the preinduction area should also be maintained at above-normal levels and patients should be covered with warm blankets during transport. Children have greater surface-area-to-body-weight ratios, resulting in more rapid heat loss.

SURGICAL CONSIDERATIONS

A general understanding of surgical management is very important for planning and perioperative management of the patient with burn injury. An appropriate surgical plan takes into account the extent, site, and depth of the burn injury; the general physical state of the patient; and the resources of the team treating the patient.[303] Typically, the first excision will be undertaken within the first 72 hours after injury (early excision). Early removal of necrotic tissue in patients with major burn injury has been associated with reduced complications including decreased infection rates, improved cardiac function, decreased overall blood transfusions, reduced hypermetabolic response, and decreased overall mortality.[304,305] However, in some cases it may be delayed until later in order to improve patient stability and/or determine how much of the burn will heal by secondary intention without need for surgery. The first excision is aimed at excision and coverage of a large portion of deep burn, and the largest areas that can be safely excised are chosen. Typically, these would be the front or back of the trunk, or large areas on the limbs. For some patients, up to 50% TBSA can be safely excised in one operation, with significantly less blood loss and hypothermia. However, for patients with comorbidities or systemic instability, the safest course is often to carry out repeated, more modest excisions spaced a few days apart until all of the full thickness burn is excised (staged excision). The extent of excision should be planned to allow the greatest advantage of available autograft or allograft skin, so that the wound may be closed immediately after burn excision. Adequate wound closure also promotes optimal hemostasis after excision. The surgeon must continually monitor the procedure in case the patient becomes unstable and a need to abort surgery becomes evident, which requires close communication with the anesthesiologists.

The most important concept with excision of burn eschar is that debridement should be carried down to a level where only viable tissue remains. Burn wound excision can be performed as either tangential or fascial excision.[303] Tangential excision removes the burn eschar in a serial fashion to a depth of viable tissue capable of accepting a skin graft, which allows for preservation of as much viable tissue as possible and usually provides a better cosmetic outcome than fascial excision. Fascial excision involves a full-thickness excision of skin and subcutaneous tissue down to the level of muscle fascia. Fascial excision is usually reserved for large, life-threatening burns where there is a need for rapid excision and is not uncommon in the older population. Advantages of fascial compared with tangential excision include its ease of dissection, less blood loss, and a well-vascularized fascial layer for skin graft placement. Disadvantages include contour deformities, permanent loss of all cutaneous sensation, and removal of lymphatics leading to lymphedema distal to the excision.

After excision or debridement of the burn wound, it is essential that the wound bed be covered since it creates a potential open portal for invasive infection. In addition, massive fluid, electrolyte, and protein loss may occur from the debrided burn wounds. Autografting is the optimal coverage; however, in massive burns either allograft or skin substitutes may be used to temporize the wound bed until autograft donor sites become available. Temporary skin substitutes provide transient physiologic wound closure giving protection from mechanical trauma, minimizing evaporative water and heat losses, and acting as a physical barrier to bacteria. These skin substitutes can also be used as a dressing on donor sites to decrease pain, enhance epithelialization, and provide temporary closure while awaiting the healing of underlying, and at times, larger injuries of widely meshed autografts. No ideal permanent skin substitute exists at present, although a number of techniques are in use, including cultured epithelial cells and dermal analogs.[306,307]

Postoperative Care

Important postoperative considerations for burn injury patients include whether to extubate in the operating room, safe transport to the ICU, transfer of care to the ICU staff, and control of postoperative pain. A phone call to the burn unit should be made in advance before completion of the surgical procedure in the operating room to allow the care team adequate time to warm the room and to obtain necessary supplies and equipment (e.g., infusions, ventilator) that will be needed on the patient's arrival to the burn unit. Transport of the patient to and from the operating room requires a systematic approach to optimize the patient's physiologic status safely. Monitors appropriate to the patient's physiologic status, transport oxygen with appropriate respiratory support, a plan to keep the patient warm, adequate transport staff, resuscitation drugs, and an easily available intravenous drug administration site are all necessary for safe transport. Patients requiring mechanical ventilation during transport need at least two anesthesia personnel or an anesthesia provider and another clinician to manage ventilation, observe the monitors, and administer medications during transport. Because patient agitation and extubation during transfer can be disastrous, providing adequate sedation and analgesia are essential during intrahospital transport and moving patients to or from the bed to the stretcher or to the operating table. Hypothermia during transport should be minimized.

Postoperatively, burn injury patients are likely to be less stable physiologically compared with the preoperative period. Continued bleeding may be concealed by dressings, the patient may be more prone to hypothermia, emergence may be associated with delirium, and analgesic requirements will be greater. During this period of exaggerated physiologic fragility, it is important to be especially vigilant during transfer of the monitors, and respiratory and hemodynamic support equipment to the ICU staff. Patients should recover in a prewarmed room as considerable heat loss can develop during transport. Radiant heaters, fluid warmers, and warming blankets are useful in maintaining normothermia.

The decision to extubate in the operating room depends on standard criteria with concerns specific to burn patients, including an assessment of airway patency, metabolic status, intraoperative fluid volumes, potential for ongoing bleeding, and when the patient will return for further surgery. Postoperative mechanical ventilation is generally indicated in patients with preoperative mechanical ventilation, as well as those undergoing delicate sheet grafting to the face/neck, in an effort to minimize motion and graft disruption in the initial postoperative days.

Inadequate control of pain and anxiety can adversely affect postoperative care increasing hemodynamic instability, causing asynchrony with mechanical ventilation, impairing wound healing, and negatively impacting psychological well-being. The presence of newly excised tissue and harvested donor sites are very painful. Burn-injured patients become quite tolerant of sedatives and analgesics over time, and thus doses substantially larger than normal doses may be required especially in the postoperative period.[308] Administering intravenous bolus doses of ketamine (approximately 0.25 mg/kg) may at times work well to break through persistent pain postoperatively that seems unresponsive to opioids.[309] The subcutaneously administered fluid and vasopressors are slowly absorbed in the postoperative period and hypertension and pulmonary edema has been noted.

Pain Management

Management of burn-related pain is extremely challenging and may change in intensity and quality over time through the multiple stages of healing.[310] Background pain is most often less of a challenge compared to mobilization pain. All aspects of burn care (e.g., dressing changes, excision and grafting procedures, physical therapy, and line insertion) are associated with pain. There can be ongoing background pain, periodic breakthrough pain, procedure-related pain, and eventually, chronic pain can develop.[311] Furthermore burn-related pain is frequently undertreated in both adults and children, especially with dressing changes and wound care.[312,313] Not uncommonly pain may occur in combination with pruritus.[314]

The painful and distressing trauma of burn injury often causes fear and anxiety in patients, which can complicate their acute care and rehabilitation, and potentially contribute to increased morbidity, mortality, and length of stay. Inadequate treatment of anxiety and pain that lead to posttraumatic stress disorder has been reported to occur in up to 30% of patients with severe burn injury. Undertreated pain may also contribute to the development of chronic pain.

The mechanism of pain in burn injury patients is multifactorial and involves the inflammatory cascades and pathways that form part of the pathophysiologic process following tissue damage and nerve injuries.[315] Excess production of mediators, including calcitonin gene-related peptide and substance P, and activation of NMDA receptors can cause sensitization of A-delta and C sensory nerve fibers.[316] As a result of these processes, patients may develop primary and secondary hyperalgesia, causing an altered or increased sensitivity to painful stimuli.[317] Even normal skin can develop abnormal sensitivity. Repeated tissue trauma and painful stimuli, such as during excision and grafting procedures and during frequent dressing changes, in conjunction with inflammatory processes and infection, can result in neuroplastic adaptations within the CNS, particularly leading to hyperexcitability of the dorsal horn of the spinal cord. Pain afferent sensory impulses undergo facilitation and amplification to a given stimulus, contributing to the generation and maintenance of chronic or persistent pain. Furthermore, these patients often show an altered pharmacodynamic and pharmacokinetic drug response, requiring a highly individualized pain management plan and effective management often requires multiple treatment modalities.

To provide appropriate, consistent patient comfort, standardized pain and anxiety guidelines are used in many burn centers.[318,319] The effectiveness of the guideline-based approach to pain and anxiety is well established. These guidelines often call for a multimodal approach including the use of opioid and nonopioid analgesics, individual titration, explicit recommendations for drug selection, dosing, and increases in dosing, use of consistent, accurate, age-appropriate pain assessment tools, a limited formulary to promote staff familiarity with drugs used, and continuous reassessment of the guideline itself. Nonpharmacologic techniques may be helpful as analgesic adjuncts in reducing pain and anxiety throughout the acute and rehabilitation stages of healing. Such methods include cognitive behavioral therapy, distraction, relaxation techniques, virtual reality, and hypnosis.[320,321]

Anesthesia providers assume an essential role in developing and refining analgesic guidelines, coordinating the multidisciplinary pain management team, and aid in the education of burn unit staff and patients. Education on pain assessment, pain control, medications, and adverse effects may take the form of consultant-led pain rounds, teaching sessions, and/or rolling training programs, which have been shown to be effective in improving pain assessment and provision of analgesia.[322]

As burn wounds are closed, the painful stimuli decrease and the need for analgesics is gradually reduced. When a patient is being weaned, opioids and other sedative doses should be gradually decreased to prevent withdrawal symptoms and still provide adequate analgesia and anxiolysis.[323] Patients may be safely extubated while still receiving opioid infusions. Pruritus is a common and often distressing problem for these patients during the healing process.[324] It can be debilitating and interfere with sleep, activities of daily living, and may cause additional tissue damage from the scratching of healing or thin epithelium and newly grafted skin leading to increased pain.[325] The causes of pruritus are multifactorial, often being triggered or worsened by opioids, heat, physical activity, and stress. Pruritus usually diminishes gradually with time but sometimes persists even after complete wound healing. A variety of approaches can control itching including systemic antihistamines, moisturizing lotions, and wearing loose-fitting clothing. Centrally acting drugs such as gabapentin and pregabalin may also be beneficial in ameliorating pruritic symptoms.[326]

Conclusion

Burn injury patients pose a myriad of challenges to acute and perioperative care. Despite significant advances in therapeutic strategies, such as improving resuscitation, enhancing wound coverage, appropriate infection control, and improving treatment of inhalation injury, severe burns remain a devastating injury affecting nearly every organ system and leading to significant morbidity and mortality. The decreasing incidence of burns in developed countries reduces exposure to burn-injured patients and underlines the need for ensuring adequate training in burn care by acute and perioperative providers. Anesthesiologists are often called on to care for burn injury patients through their hospitalization including acute airway management and resuscitation, intraoperative anesthetic care, intensive care, and management of postoperative pain. To optimally care for this challenging patient population requires understanding, appreciating, and anticipating the unique preoperative, intraoperative, and postoperative issues and problems of the burn injury patient that predispose them to increased morbidity and mortality.

Occupational Safety, Infection Control, and Substance Abuse

CHRISTOPHER CHOUKALAS, MARILYN MICHELOW, and
MICHAEL FITZSIMONS

KEY POINTS

- Exposure to waste anesthetic gas in clinical practice is unavoidable. In the United States, the limits of exposure to waste gases are set by the National Institute for Occupational Safety and Health (NIOSH), which recommends a time-weighted average of 25 ppm for nitrous oxide and a ceiling of 2 ppm for volatile anesthetics.
- Although researchers disagree whether exposure to anesthetic gases at concentrations less than NIOSH limits affects health or performance, these limits are often exceeded. If it can be smelled, the exposure is many times greater than the safe limit.
- Occupational exposure to radiation comes primarily from x-rays scattered by the patient and surrounding equipment. A distance of 3 feet from the patient is recommended to minimize physiologic damage from occupational exposure, and a distance of 6 feet from the patient provides the same protection as 2.5 mm of lead.
- Surgical smoke is increasingly recognized as a source of potentially infectious and carcinogenic material; evacuation devices should be used where the smoke plume is created.
- Diseases can be transmitted via direct contact, droplets, or airborne particles. Some diseases are infectious only if there is direct exposure to blood or body fluid from the host. Appropriate personal protective equipment based on the suspected type of infection should always be used to prevent occupational disease transmission.
- To attenuate occupational exposure to pathogens, standard precautions at a minimum should be used at all times. The appropriate barrier precautions for intubation include eye protection, a surgical mask, and gloves.
- To prevent exposure to bloodborne pathogens, sharps safety, including the use of safety retractable needles and needleless systems, should be used.
- Occupational exposure to human immunodeficiency virus (HIV) and hepatitis B and C viruses (HBV and HCV) is most often the result of a percutaneous injury. The risk of disease transmission is generally very low but is greatest from hollow-bore needles, needles contaminated with visible blood, and exposure to a source patient with high viral titer.
- Postexposure prophylaxis (PEP) is recommended after occupational exposure to HIV or HBV. The recommended guidelines for PEP are available on the Centers for Disease Control and Prevention website. The Clinical Consultation Center PEPline service is a free expert resource for guidance on PEP (1-888-448-4911).
- The preference for and access to potent opioids contribute to the prevalence of substance use disorder among anesthesiologists. The rate of drug-related deaths is more than twice as high in anesthesiologists as internists.
- Although many recovered anesthesiologists return to the practice of anesthesia, there is a significant relapse rate. The chance of relapse is highest in physicians who become addicted to potent narcotics early in their career. Successful recovery requires a lifelong commitment to treatment. In some cases, a change in specialty is the only solution.
- Sleep deprivation has an adverse effect on physician mood, cognitive function, reaction time, and vigilance. Although sleep deprivation and fatigue adversely affect clinical performance, the full impact on patient outcome has been difficult to determine.

The practice of anesthesiology exposes its practitioners to a variety of risks unique among medical specialties. Some of these risks are tangible or physical, such as waste anesthetic gases and communicable disease, whereas others are more insidious, such as stress, fatigue, and the risks of substance abuse disorder. Each of these risks can be mitigated but probably not eliminated.

In the case of physical exposures such as waste anesthetic gases, radiation, and bloodborne pathogens, efficient gas scavenger systems, the use of protective lead, needle-shielded intravenous (IV) lines, standard precautions (SP), and postexposure prophylaxis (PEP) protocols are currently commonplace in contemporary anesthesia practice. The less tangible risks are harder to reduce. Work hour restrictions may limit fatigue among housestaff; however, doing so may not improve patient outcomes, particularly when such controls do not apply to practicing physicians. Substance abuse disorders remain a problem with a multifactorial etiology and few clear solutions. This chapter examines the risks associated with each of these environmental and situational hazards, and reviews the measures one can take to avoid them.

Physical Exposures

INHALATIONAL ANESTHETICS

Volatile inhaled anesthetics are an indispensable part of anesthesia practice; however, these agents also have the potential to cause harm to patients and the physicians caring for them. Given what is suspected about their impact on patient health, vis-à-vis neurodevelopment of the very young, the spectrum of postoperative cognitive dysfunction in adults, and immunosuppressant effects on patients of all ages,[1] it is natural to wonder whether these compounds are harmful to health care workers exposed to them on a daily basis.

Definitive answers remain elusive; it is difficult to randomize exposure, and previous work suggesting a link between exposure to waste anesthetic gas and infertility and other health effects suffered serious methodologic flaws. Still, the topic of the impact of exposure on cognitive performance and health continues to generate more questions than answers.

Waste nitrous oxide (N_2O) and halogenated anesthetics in the absence of scavenging may approach concentrations as high as 3000 and 50 ppm, respectively.[2] This is relative to guidelines for safe practice, which historically have proposed limits of exposure well below (e.g., 25 ppm N_2O and 2 ppm of any halogenated agent).[3] Although the concentration of waste gases can be well controlled with proper scavenging, in practice the levels recommended by the National Institute for Occupational Safety and Health (NIOSH) are often exceeded during the routine delivery of anesthesia.[4,5] Although exposure to anesthetic gases is more common in pediatric anesthesia where mask inductions and uncuffed endotracheal tubes are more commonly used, the introduction of the laryngeal mask airway to anesthesia practice may increase operating room exposure to waste gases in adult cases as well. One study of inhaled induction of anesthesia and maintenance with sevoflurane and N_2O in adults resulted in violations of NIOSH standards 50% of the time.[6]

Provider Health Effects

One of the first examinations of the impact of exposure to subanesthetic concentrations of inhalational anesthetics on cognitive performance was conducted by Bruce and Bach in the 1970s. They noted that healthy volunteers in the laboratory suffered a decrease in psychomotor performance when exposed to concentrations of N_2O as low as 50 ppm, alone or in combination with 1 ppm of halothane. The same study showed that 25 ppm of N_2O combined with 0.5 ppm of halothane had no effect.[3,7] Subsequently, three other groups of researchers studying volunteers in laboratories have been unable to confirm the earlier findings. The lack of agreement between investigators has led some to conclude "that there is no convincing evidence that anesthetics in concentrations equal to those found in unscavenged operating theatres have any effect on the psychomotor performance of healthy subjects in the laboratory."[8] A study conducted on volunteers in an operating room during normal clinical activities in which trace concentrations of N_2O and halothane ranged from 0 to 2300 and 0 to 37 ppm, respectively, also failed to detect impairment in psychomotor performance.[9] In contrast, a series of studies in healthy volunteers showed that subanesthetic concentrations of N_2O, isoflurane, and sevoflurane were associated with reductions in psychomotor performance, with some studies suggesting a dose-dependent effect for N_2O dose as low as 10% and a sevoflurane dose as low as 0.4%.[10-12] By way of comparison, 10% N_2O is equivalent to 100,000 ppm, significantly higher than the recommended safe level of exposure and the level of exposure in the Bruce and Bach studies. Whether the methods in these studies closely mimic patterns of occupational exposure in clinical practice is debatable, but it must be acknowledged, as discussed later, that occupational exposure may greatly exceed accepted safe levels.

Fetal Health Effects

Anesthetics have been implicated in the development of cancer, spontaneous abortions, and genetic and developmental anomalies. The possibility that chronic exposure to anesthetic waste gases could result in adverse health effects was first appreciated in the late 1960s, when a report of potential harm appeared in the Russian literature; Vaisman reported an increased incidence of abortions (18 spontaneous abortions in 31 pregnancies) among female anesthetists.[13] After this initial report, a multitude of retrospective studies followed. Of these, three large studies conducted during the 1970s and 1980s in the United States and the United Kingdom all concluded that the prevalence of spontaneous abortion was substantially higher in female anesthesiologists than in female physicians working outside the operating room.[14-17] Studies in this era also concluded that the incidence of congenital anomalies in children of male and female anesthesiologists was higher than in the control groups of physicians.[18-20] In addition to these reproductive effects, meta-analysis of six of these early studies linked the exposure to anesthetic gases to hepatic disease in male anesthesia personnel[21] and cervical cancer, liver disease, and kidney disease in female anesthesia personnel.[22] A number of studies with similar methodologies failed to detect a relationship between exposure and health.[23-25] Although many of these older studies suffered from significant methodologic limitations,[14,15,21] a 1997 meta-analysis of more than 19 studies completed between 1984 and 1992 reported a relative risk of abortion in female subjects exposed to anesthetic gases to be 1.48 (confidence interval [CI] 95%, 1.4-1.58).[26]

The Task Force on Trace Anesthetic Gases was convened by the American Society of Anesthesiologists (ASA) Committee on Occupational Health of Operating Room Personnel to analyze data from all available epidemiologic studies. The methodologic flaws in the studies impaired the task force's ability to draw conclusions about an association between occupational exposure to waste anesthetic gases and adverse health effects. Their report, published in 2002,[27,28] cited data from a prospective survey[29] of 11,500 U.K. female physicians documenting occupation, work practices, lifestyle, and medical and obstetric history, as well as hours of exposure and the use of scavenging equipment. This report showed the incidence of infertility, spontaneous abortion, and children with congenital abnormalities in female anesthesiologists to be the same as that in other physicians.[29] The position of the ASA is that "There is no evidence that trace concentrations of waste anesthetic gases cause adverse health effects to personnel working in locations where scavenging of waste anesthetic gases is carried out" and "the general conclusion… is that currently used anesthetics… have no mutagenic potential."[27,28] This reassurance may be of little comfort in light of evidence and clinical experience that show levels of exposure in clinical practice routinely exceed those considered safe by health and regulatory agencies.[4,5] The task force document also summarized contemporaneous recommendations from the Occupational Safety and Health Administration (OSHA) recommending that from the employee's "Right to Know," there are "potential adverse effects of exposure to waste anesthetic gases such as spontaneous abortions, and congenital abnormalities in children."[27,28]

Subsequently, there have been several more studies that support the possibility of an intrauterine effect. An analysis of Canadian nurses identified significant odds of congenital anomalies in the offspring of nurses working in settings with exposure to waste anesthetic gases compared with those working in settings where the likelihood of exposure was lower.[30] Subsequent research using chromosomal and molecular DNA analysis identified correlations between exposure and genotoxic effects (e.g., sister chromatid exchanges, breaks in DNA, and chromosomal abnormalities)[31-33] but did not examine clinical outcomes in offspring. However, these more recent epidemiologic and genetic studies did not quantify exposure but rather assumed exposure by selecting health care workers from settings where exposure was assumed to have taken place.

Given the study limitations, the lack of consensus or updated ASA guidelines, and the findings that safe inhalational anesthetic levels may often be exceeded, it must be acknowledged that harm is possible. Manufacturers of anesthesia work stations, health care systems, and clinicians must remain vigilant to reduce risk.

Mitigating Health effects

The potential health effects of occupational exposure to anesthetic gas can be mitigated through waste anesthesia gas scavenging systems, establishing levels of safe exposure, auditing exposure levels, and enforcing recommended frequencies of air exchanges in locations where anesthesia gas may be found (e.g., operating rooms, procedural suites, and recovery areas).

Although the universal use of scavenging systems is critical to safe, modern anesthesia practice, it can lead to a false sense of security among operating room personnel. Kanmura and colleagues[34] found abnormally high ambient concentrations of N_2O in 402 delivered anesthetics, of which 42% were the result of mask ventilation, 19.2% a disconnected scavenging system, 12.5% a leak around pediatric endotracheal tubes, and 11.5% equipment leakage. Furthermore, all of the scavenging system disconnects in this study were attributed to human error rather than equipment failure.[34] Because most anesthesia machines were not equipped to recognize disconnected scavenging systems, a fault that has been corrected on most modern anesthesia machines, a failure of the system on older machines may not be readily apparent. Diligent maintenance and a thorough understanding of anesthesia scavenging systems are essential to comply with NIOSH standards and to minimize operating room exposure. Emerging evidence exists for the role of various activated charcoal compounds to absorb molecules of anesthetic vapor,[35] but these have been trialed only in experimental settings and are not yet available commercially.

Regulations and recommendations regarding workplace safety are established by several governmental agencies. The OSHA is the national agency within the U.S. Department of Labor that sets and enforces standards to ensure "safe and healthful working conditions." The Centers for Disease Control and Prevention (CDC) and NIOSH are both federal agencies conducting research and making recommendations regarding health and workplace safety. Unlike OSHA, neither the CDC nor NIOSH are regulatory agencies. State and local health departments, as well as hospital infection control departments, are also tasked with enacting and enforcing health care workplace safety standards.

The NIOSH sets recommended exposure limits for the operating room setting, stating "no worker should be exposed … [to] concentrations greater than 2 ppm of any halogenated anesthetic or 25 ppm of N_2O" in the 1970s.[3] These exposure limits have not been updated nor do they include newer volatile anesthetic drugs. These exposure levels were selected based on the lowest level known at the time to cause side effects (50 ppm N_2O or 1 ppm of halothane caused cognitive impairment in dental students)[36] and the level that could be easily and practically achieved.[37] Subsequently, it was realized that the data used to set the standards might not be generalizable because the subjects were Mormon, a subgroup likely more sensitive to depressant drugs[38]; a more recent study with a small sample size showed cognitive impairment at 50 ppm of N_2O,[39] levels that are routinely found in studies[4,5,40,41] and are well above the NIOSH levels. The threshold of perception of halothane ranges from less than 3 to more than 100 ppm.[2] If the anesthetic can be smelled, its concentration is likely to be many times greater than the maximum recommended level.

Occupational exposure is not limited to operating room staff, because patients continue to exhale trace amounts of N_2O for 5 to 8 hours postoperatively.[42] Sessler and Badgwell used lapel dosimeters to measure the concentrations of volatile anesthetics of recovery room nurses during the first hour of PACU care in patients who had received inhaled anesthetics. In this study, breathing zone anesthetic concentrations were in excess of NIOSH recommendations in 37% of patients who received isoflurane, 87% of patients who received desflurane, and 53% of patients who received N_2O.[43] A more recent but similar study reported a much lower average concentration (3.1 ppm) of N_2O in the breathing zone of recovering patients in a Canadian PACU,[42] also above the recommended safe levels of exposure. These studies demonstrate the importance of proper ventilation in PACUs. Both groups reported PACU room air exchanges of 8 volumes per hour, although much of the air in the Sessler and Badgwell study was recirculated. N_2O levels can be reduced to undetectable levels with air exchanges of 20 per hour, with 25% of each exchange taken from fresh air.[27] Although OSHA does not currently regulate exposure to N_2O and halogenated anesthetics, the agency does provide guidelines designed to minimize workplace exposure. These include the appropriate assembly and monitoring of scavenging systems, the detection and correction of machine leaks, and the installation of effective ventilation systems.[44] In the operating room, the recommended air exchange rate is a minimum of 15 air exchanges per hour, with at least 3 air exchanges of outdoor air per hour. Laminar flow is better than turbulent flow with regard to measured levels of exposure.[4] In the PACU, at least 6 air changes are recommended, with a minimum of 2 exchanges of outdoor air per hour. OSHA recommends air sampling for anesthetic gases be performed on a biannual basis and records of air sampling methods, locations, dates, and concentrations measured, as well as results of anesthesia machine leak tests, be maintained for at least 20 years. Although OSHA is a government agency, these recommendations are not legally mandated.[27,28]

In summary, the possibility that waste anesthetic gas at levels routinely encountered in clinical practice could cause deficits in performance and human health remains. Caution must be exercised, and clinicians should limit their exposure as much as possible.

RADIATION

The anesthesiologist is routinely exposed to both ionizing and nonionizing electromagnetic radiation. The former is primarily from x-rays and occasionally from radioactive isotopes that release gamma rays, and the latter is from lasers. Less common is contact with ionizing radiation from radioactive isotopes that release either alpha or beta particles. Ionizing radiation has enough energy to create both free radicals and ionized molecules in tissues by driving electrons completely out of their stable orbitals. If the radiation exposure is severe enough, tissues may be destroyed or chromosomal changes may cause malignant growth. Nonionizing radiation may excite electrons to move from the ground state to higher orbitals in molecules, but the electrons remain in the molecule. In this case, damage to tissues may result from the heat produced by the absorbed radiation.

Ionizing Radiation: X-rays

In the past, exposure to radiation occurred mostly in the operating room with the use of portable fluoroscopy and x-ray machines. Advancements in endovascular surgery, hybrid cardiac surgery procedures, electrophysiology studies, and other imaging procedures significantly increase exposure of anesthesia personnel to ionizing radiation[45] relative to traditional operating room cases. Radiation is undetectable with our normal senses, so a basic understanding of its features will minimize exposure.

TABLE 88.1 Relevant Exposure Limitations for X-Rays

	OSHA*		ICRP†	
Region	rem	mSv	rem	mSv
Head, eyes, gonads	5	50	2	20
Hands, wrists	75	750	50	500
Skin of the whole body	30	300	50	500
Pregnancy	0.5	5	0.1	1

*Occupational Safety and Health Administration.[47]
†International Commission on Radiological Protection.[48]

One Sievert (Sv) is equal to 100 rem and is a measure of the biologic damage from radiation adjusted to apply to all tissues.[46] Estimates of radiation exposure from natural sources vary, depending on geographic location. The average in the United States ranges from 0.8 to 2 mSv (80-200 millirem [mrem]) per year. Natural radiation comes primarily from cosmic rays (approximately 0.4 mSv at sea level, with an increase of 0.1 mSv/1000 feet), as well as from radioactive compounds found in soil, brick, and concrete. For most physicians, the additional radiation from occupational exposure is no greater than that from natural sources. OSHA sets limits of occupational exposure (expressed as rem) that vary by body area; allowable limits are higher for the hands than for the whole body, gonads, or blood-forming parts of the body.[47] An easy rule of thumb is 5 rem (50 mSv) per year, with no more than 1.25 rem (12.5 mSv) in any given calendar quarter. In 2007 the International Commission on Radiological Protection, an international nonprofit, proposed more stringent limits than those proposed by OSHA (Table 88.1), and both agree that limits should be lower for personnel who are pregnant.[48,49]

Occupational exposure to radiation comes primarily from x-rays scattered by the patient and the surrounding equipment, rather than directly from the x-ray generator itself.[50] One chest radiograph results in approximately 25 mrem of exposure to the patient; procedures requiring multiple films occasionally involve more than 1 rem. The amount of radiation generated during fluoroscopy depends on how long the x-ray beam is on; just as light is reflected from surfaces, x-rays are reflected from the surfaces on which they impinge. This scattering accounts for most occupational exposure. Research findings vary about the degree of exposure typical for anesthesia providers, but most studies show low levels of exposure.[45,51-53] Recent studies have compared risk profiles of various positions of the anesthetist and the x-ray beam. A simulation-based study using phantom patient and anesthetist models with dosimeters demonstrated that exposure was greater near the head of the bed (vs. along the sides of the bed) or when the x-ray beam was in either of the lateral positions (e.g., shooting cross-table images).[54] A real-time evaluation of exposure in personnel conducting transesophageal echocardiography (TEE) during transcatheter aortic valve replacement showed that the TEE operator receives 5 times as much radiation as other clinicians involved in the procedure.[55] Furthermore, this exposure is heightened by the use of oblique angles for imaging. Notably, by using additional shielding (e.g., a ceiling-mounted lead acrylic shield), this exposure was reduced by more than 80%.

Mitigating Health Effects

Radiation physicists recommend the "As Low As Reasonably Achievable" guiding principle for radiation exposure to both the patient and practitioner. Technologic innovation leading to advances in imaging technology and industrial design may further limit exposure.[56,57]

Because the intensity of scattered radiation is inversely proportional to the square of the distance from the source, the best protection is physical separation. A distance of at least 3 feet from the patient is recommended. Six feet of air provides protection the equivalent of 9 inches of concrete or 2.5 mm of lead.[58] Using studies of real-time dosimeters and simulation studies using phantom patients, a recent systematic review found that at a 4.9-foot (1.5 m) distance from the x-ray source, exposure was no greater than that due to background radiation.[51] This finding has been replicated in a handful of studies of clinical exposures.[45,52] The authors go so far as to question the need for anesthesia personnel to wear lead aprons, which conflicts with OSHA recommendations.[59] Although they may be uncomfortable, aprons containing the equivalent of 0.25 to 0.5 mm of lead sheet are effective in blocking most scattered radiation and such devices are recommended to be worn whenever there is an exposure risk.[60] Uncovered areas, such as the lens of the eye, still bear the risk of injury,[50] and radiation dose to the eyes varies with the type of surgery and the position of the anesthesiologist relative to the patient and x-ray field.[54,61] OSHA recommends opaque goggles for health care workers in the "direct x-ray field."[59]

Nonionizing Radiation: Lasers

Laser is an acronym for light amplification by stimulated emission of radiation. Lasers produce infrared, visible, or ultraviolet light. A surgical laser produces intense, focused electromagnetic radiation to cut or destroy tissues. Although the radiation from lasers is nonionizing, it is potentially unsafe both because of its intensity and because of the matter released from tissues during treatment.

Of those in common clinical use, carbon dioxide and neodymium:yttrium-aluminum-garnet (Nd:YAG) lasers emit light in the far-infrared and near-infrared wavelengths, respectively; argon and tunable dye lasers produce visible light.[62]

Eye injuries are the greatest risk to personnel working near lasers. Strict standards for protection have been developed based on current understanding but are subject to periodic revision. Either direct exposure or reflected radiation may cause eye damage. Injuries include corneal and retinal burns, destruction of the macula or optic nerve, and cataract formation. Protective eyewear is designed to filter out the radiation produced by a specific type of laser while still permitting vision. For example, clear plastic lenses block the far-infrared (10,600 nm) radiation from carbon dioxide lasers but provide no protection against the near-infrared (1064 nm) radiation emitted by Nd:YAG lasers. The type of protection provided by a given filter is marked on the frame of the goggles and should be checked before use. Filters that are scratched should not be used. Because certain filters block portions of the visible spectrum, it is prudent to confirm preoperatively that patient monitors can be seen and interpreted correctly with goggles in place. Protective eyewear is recommended for all exposed personnel because reflected radiation can be as hazardous as direct radiation and, unlike x-ray radiation, the intensity is not diminished significantly by the distance traveled in the average operating room.[62]

In addition to direct injury from laser light, clinicians should avoid the smoke plume created by lasers.[63-65] Under experimental conditions, viable bacteria have been recovered from the plume emanating from laser irradiation,[66] as have compounds known to be carcinogens and environmental toxins.[63] Intact DNA from human papillomavirus (HPV) has been detected in the vapor from both laser-treated plantar warts and genital condylomata[67,68] and on the gloves of treating physicians.[69] Human immunodeficiency virus (HIV) proviral DNA has been found in laser smoke produced by vaporizing cultures of HIV-positive cells.[70] Although these experiments, which used tissue cultures, do not replicate routine clinical circumstances, they stress the importance of strict attention to smoke removal. Simulation studies confirm that concentrations of laser-generated particulate matter are higher near the operating field than elsewhere in the room, sometimes by a factor of four, regardless of the degree of room ventilation.[64]

As an extreme example, a case report documented the appearance of laryngeal papillomas in a laser surgeon who had previously treated several patients infected with anal condylomata without the benefit of a laser smoke evacuator.[71] Tissue from the surgeon's laryngeal tumors contained HPV DNA types 6 and 11, the same viral types that are commonly harbored by anogenital condylomata. Hence it is prudent to scavenge all vaporized debris.

SURGICAL SMOKE

Increasing attention is focused on the health effects of exposure to surgical smoke created by electrocautery and ultrasonic scalpels.[72] Data suggest that smoke from electrocautery contains infectious and malignant cells, albeit in small quantities, as well as carcinogenic compounds.[73] Ultrasonic scalpels can produce viable cells in the smoke plume, as demonstrated in a study that showed that the malignant cells grew cancer when subsequently injected into mice.[74]

Data from a NIOSH survey of health care workers shows that the majority of operating room personnel believe local exhaust ventilation devices (e.g., smoke evacuators on the surgical field) are not routinely in use.[75] Respondents reported that a lack of institutional protocols and a belief that exposure was minimal or not concerning were responsible for the lack of such protective strategies. Anesthesia personnel are intimately familiar with the various odors common in our practice; the smell of flesh burned with electrocautery should be a signal to those in the operating room that they are being exposed to potentially harmful material.

Mitigating the effects of exposure to surgical smoke is a critical endeavor. Most standard surgical masks trap only the largest of the smoke particles,[76] and standard surgical masks are demonstrably ineffective at filtering particles generated

TABLE 88.2 Occupational Exposure, Risks, and Safety Measures

Exposure	Sources	Potential Risks	Protection
Inhalational agents	Free gases Mask inductions Use of LMA Agent spill Inadequate scavenging	Infertility Decrease in psychomotor performance Cancer development Spontaneous abortion Hepatic disease Congenital abnormalities	Scavenging systems Air exchange Use mask induction appropriately Activated charcoal filters
Ionizing radiation	Portable fluoroscopy Hybrid operating rooms Interventional suites	Cancer Eye damage Infertility	Distance >3 feet from source Lead aprons Leaf shields Lead surgical caps Periodic radiation monitoring
Nonionizing radiation	LASER	Eye injury Vaporization of bacterial or viral matter	Protective eyewear Laser-specific surgical masks
Microdebris from smoke	Surgical cautery Ultrasonic scalpel	Exposure to bacterial, viral, and carcinogenic matter	Surgical smoke evacuators FFP 2 particulate masks

by laser.[77,78] Even laser-specific masks were many-fold less effective at particle removal than the comparator, a protection class FFP level 2 dust and fine particle mask.[77] The median size of particles in plume samples obtained intraoperatively is 0.31 μm in diameter (range, 0.1-0.8 μm). Even after filtration of particles greater than 0.5 μm in diameter, exhaust smoke from tissues treated with a carbon dioxide laser causes pulmonary lesions in laboratory animals. If all particles larger than 0.1 μm are scavenged, no lung damage occurs, emphasizing the importance of scrupulous removal of the plume,[70,79] a practice advocated by the CDC, OSHA, and the Association of Perioperative Registered Nurses.

By using adequate evacuation and filtration equipment specifically designed to scavenge such vapors, it may be less likely that operating room personnel will be contaminated by laser-dispersed HPV DNA.[67] However, laser-specific surgical masks should also be used whenever lasers are in use, and institutions should evaluate the use of smoke evacuators for the surgical field (Table 88.2).

Infectious Exposures

Understanding the basic principles of infection control is essential to the safe and responsible practice of anesthesia.

INFECTION PRECAUTIONS

Infection control standards have changed dramatically over the past 50 years, with the introduction of protocols for handwashing, use of personal protective equipment (PPE), incorporation of environmental controls, and implementation of sharp safety devices.

Beginning in 1985 in response to the HIV/AIDS epidemic, the CDC released recommendations for "universal precautions" to be used by all health care workers exposed to blood or body fluids, regardless of the infectious status of a patient.[80] These recommendations were expanded in 1996 into the concept of standard precautions (SP), which are to be used with all patients at all times. The CDC also introduced airborne, droplet, and contact transmission-based precaution guidelines for diseases spread by those specific routes.[80]

Standard Precautions

SP encompass hand hygiene between every patient contact event, before aseptic tasks, and after contact with bodily fluids. Hand hygiene includes both the use of plain or antibacterial soap and water and the use of alcohol-based gels without water. Unless hands are visibly soiled, hand hygiene with an alcohol-based gel has greater antimicrobial effect and is preferred to soap and water.[81] It is estimated that every anesthesia procedure presents at least 25 hand hygiene opportunities and hundreds of contact events with the patient and then surfaces in the anesthesia environment but that anesthesiologists are compliant with hand hygiene recommendations only approximately 1% to 10% of the time.[82,83] Importantly, using gloves does not obviate the need for hand hygiene, because 1% to 2% of examination gloves have microperforations that can allow bacteria to penetrate the glove surface.[84]

SP include the application of PPE such as a gown, gloves, a mask, or eye protection as appropriate during patient-care activities likely to expose a health care worker to a patient's blood or secretions. The need for PPE differs depending on the specific task at hand. During intubation, it is recommended that the anesthesiologist perform hand hygiene and use gloves, a mask, and eye protection.[85] One study estimated the frequency of glove use by anesthesiologists during intubation, extubation, and IV line placement at only 10% for attending anesthesiologists and 50% for trainees.[86]

When a patient is known or suspected to have an infection transmitted by a specific route, such as contact, airborne particles, or droplets, specific transmission-based precautions should be used in addition to SP. These precautions are discussed in more detail later.

When transporting a patient on transmission-based precautions, it is important to ensure that the infectious areas of the patient are appropriately contained. For example, if a patient is on airborne precautions for active TB, then the patient should wear an N95 mask or higher during transport. If a patient is on contact precautions, the patient should be covered in a gown or sheets and providers should wear clean PPE during transport.[80]

TABLE 88.3 Immunizations Recommended for Health Care Workers

Infection	Risk to Health Care Workers	Immunization	Special Considerations
Hepatitis B	Percutaneous or mucosal exposure to infectious blood/body fluid	3-dose series at 0, 1, and 6 months	Approximately 1% receiving the complete series will not have full immunity
Influenza	Infectious transmission via droplet route	Yearly	Effectiveness of vaccine varies with year
Measles, mumps, rubella	Infectious transmission through droplet and airborne routes	2-dose vaccine for measles, mumps and rubella together (usually as a child)	1% of health care workers who were vaccinated may have lost immunity
Pertussis	Contact or droplet transmission	Every 10 years (usually as Tdap with tetanus and diphtheria toxoids)	Even immunized health care workers need postexposure prophylaxis
Varicella	Contact or airborne transmission	2-dose series (not needed if history of past varicella infection)	

Information from Immunization of health-care personnel, recommendations of the Advisory Committee on Immunization Practices (ACIP), Centers for Disease Control and Prevention 2011- REF 20.

Environmental Controls

Environmental controls are additional safety measures used to prevent the spread of airborne infectious particles; examples in hospitals include engineering systems to manage ventilation (e.g., negative pressure rooms), use of high-efficiency particulate air (HEPA) filtration, frequent air exchange rates, and ultraviolet irradiation of air in the upper portion of a room or in air ducts.[87,88] Because operating rooms are kept at positive pressure with respect to hallways (to prevent the introduction of infectious particles into a sterile area), elective procedures on patients with active TB or other airborne diseases should be postponed. If it is not possible to delay surgery, the procedure should be performed in an operating room with an anteroom.[89] A HEPA filter should be placed in the circuit after the Y-connector, to prevent contamination of the anesthesia machine.

Needlestick and Sharps Safety

A key element of universal precautions and SP is the prevention of injuries due to sharps and the use of safe injection practices. In 2000 the CDC estimated that health care workers experience more than 600,000 needlestick and other percutaneous injuries yearly.[90] OSHA has developed standards to protect health care workers from exposure to bloodborne pathogens. These standards were most recently updated in 2001 after the passage of the federal Needlestick Safety and Prevention Act of 2000.[91] OSHA standards mandate that employers make available safety-engineered sharps devices, provide for safe disposal of sharps, make appropriate PPE available, offer free hepatitis B virus (HBV) vaccination to workers who have been exposed to potentially infectious fluids, and have procedures for medical evaluation and PEP for employees exposed to bloodborne pathogens.[92] With the implementation of safety-engineered sharps, overall needlestick injury rates have dropped significantly from before 2000 to after 2004, in some studies, by well over 50%.[93]

The risk of a sharps injury correlates with medical specialty and clinical experience. The Duke Health and Safety Surveillance System Study quantified the risk of percutaneous exposures to body fluids by various health care worker groups. In this study, anesthesia residents had 19 needlestick events per 100 residents per year, compared with an exposure rate for all anesthesia providers of 6.9 events per 100 employees per year and an overall exposure rate of 3.9 events per 100 full-time employees.[94] In addition, night work and shifts lasting greater than 24 hours were associated with an increased rate of needlestick injury.[95]

Injuries from the use of hollow-bore needles account for more than half of sharps injuries.[90] Percutaneous injuries can occur during and after use of a sharp device. Wearing gloves, double gloving, and avoiding recapping needles by using a two-handed technique can reduce the risk of a needlestick injury.[90,96] In addition, the use of a curved suture needle with a needle holder for suturing is safer than the use of a handheld straight suture needle.[97]

Accidental needlesticks are underreported. The CDC estimates that only approximately 54% of percutaneous exposures are reported to occupational health, perhaps because of fears that reporting will be time consuming or nonconfidential.[98] All occupational needlesticks and exposures should be reported to a hospital occupational health program for evaluation, testing, and possible PEP.

Vaccine Preventable Illness

The CDC Advisory Committee on Immunization Practices recommends that all health care providers be vaccinated against a variety of vaccine-preventable diseases to reduce the risk of occupational exposure and transmission of these pathogens (Table 88.3).

The most up-to-date infection control guidelines are available at the CDC website.[99] Recommendations for infection control specific to the practice of anesthesia have been published by the ASA Committee on Occupational Health Task Force on Infection Control.[6]

TRANSMISSION OF INFECTIOUS AGENTS

Anesthesia providers are exposed to a wide range of infectious pathogens, including bacteria, viruses, fungi, parasites, and prions. The three principle routes of pathogen transmission are via contact, droplet, and airborne spread. Bloodborne infectious agents, such as HIV and HBV, are transmitted to the health care worker via percutaneous injuries or direct contact of nonintact skin or mucous membranes with infected blood or other serum derived body fluids (Table 88.4).[100,101]

Contact Transmission

Contact transmission, the most common type of infectious transmission,[80] can either be direct, from an infected person to another person, or indirect, with a contaminated

TABLE 88.4 Infectious Precautions for Selected Transmissible Diseases*

Infection	Type of Infectious Precaution	Special Considerations
AIDS/HIV	Standard	Standard precautions include needlestick safety. Postexposure prophylaxis indicated for some exposures
Aspergillosis	Standard	
Clostridium difficile	Contact	Handwashing is required after patient contact, spores are not removed with alcohol-based gels
Ectoparasites (i.e., lice, scabies)	Contact	
Gastroenteritis	Standard	Contact precautions if rotavirus, or if the patient is diapered or incontinent
Hepatitis (A-E)	Standard	Postexposure prophylaxis may be indicated for HBV percutaneous exposure
Herpes simplex Severe primary mucocutaneous All other infections (including encephalitis)	Contact Standard	Until lesions are dry and crusted
Herpes zoster (Varicella-zoster) Local Disseminated	Standard Airborne, Contact	Nonimmunized health care workers should not enter room if immunized caregivers are available.
Influenza	Droplet	Postexposure prophylaxis may be indicated in some circumstances
Measles	Airborne	Nonimmunized health care workers should not enter room if immunized caregivers are available.
Meningococcal disease	Droplet	Postexposure prophylaxis may be indicated in some circumstances
Mumps	Droplet	Nonimmunized health care workers should not enter room if immunized caregivers are available.
Multidrug resistant organisms (including MRSA, VRE, ESBLs)	Standard or Contact	Contact precautions are recommended in settings with evidence of ongoing transmission, acute care settings, or wounds that cannot be contained by dressings
Pertussis	Droplet	Postexposure prophylaxis may be indicated in some circumstances
Prion diseases	Standard	Use special sterilization procedures for contaminated surgical equipment
Respiratory syncytial virus	Contact	Use mask for actively coughing patient according to standard precautions
Rhinovirus	Droplet	
Rubella	Droplet	Nonimmunized health care workers should not enter room if immunized caregivers are available.
Severe acute respiratory syndrome (SARS)	Airborne, Droplet, Contact	
Staphylococcus (excluding MRSA) Major draining wounds Minor wounds or infections	Contact Standard	
Streptococcus (group A)	Droplet Contact-only for major wounds	Droplet if major infectious, involves the respiratory tract. Standard precautions if a minor or limited infection
Tuberculosis (active) Pulmonary Extrapulmonary	Airborne Airborne, Contact*	Contact if active draining lesions present
Viral hemorrhagic fevers (including Ebola, Marburg, Lassa)	Droplet, Contact, and Airborne	

*Excerpted from Appendix A. Type and duration of precautions recommended for selected infections and conditions. Centers for Disease Control and Prevention (CDC) 2007 guideline for isolation precautions: preventing transmission of infectious agents in health care settings.[80]

HBV, Hepatitis B virus; *MRSA*, methicillin-resistant *Staphylococcus aureus*.

intermediate such as a laryngoscope handle in an operating room.[102] When a patient has a contact-transmitted infection, contact precautions should be used at all times. These include keeping patients separated at least 3 feet from neighbors and wearing a gown and gloves for all patient-care interactions. Examples of microorganisms commonly transmitted via contact include respiratory syncytial virus, herpes simplex virus, *Staphylococcus aureus* (including methicillin-resistant *S. aureus*), and scabies.[80]

Clostridium difficile is an epidemiologically important contact-transmitted organism in health care facilities. *C. difficile* is a gram-positive spore-forming anaerobe that causes diarrhea and pseudomembranous colitis. The use of broad-spectrum antibiotics such as cephalosporins, clindamycin, and vancomycin are associated with *C. difficile* infection. Notably, *C. difficile* spores are not removed by the use of alcohol-based hand disinfectants. Health care workers who are in contact with patients suspected of having *C. difficile* infection should use contact precautions at all times and wash hands with soap and water after patient contact.[80]

Norovirus, a single-stranded RNA virus, is an important contact-transmitted organism and the most common cause of acute gastroenteritis in health care settings.[103] Health care workers should use standard and contact precautions any time a patient presents with diarrheal symptoms. Health care workers who contract norovirus should check with their institutional policy, which may require that the worker be excluded from work for at least 24 hours after symptoms have resolved.[103]

Parasitic skin diseases caused by lice and scabies are also spread via contact transmission. Anesthesiologists should be aware of the highly contagious nature of these conditions and use a gown and gloves for all interactions with patients who have an undiagnosed rash or are suspected of carrying ectoparasites. PEP is not routinely recommended.[104]

Droplet Transmission

Droplet transmission occurs when an infectious agent travels a short distance directly from the respiratory tract of an infected source to a susceptible mucosal surface in a recipient.[80] Droplet transmission can occur during intubation, airway suctioning, or if the patient coughs or sneezes.[105] The risk of droplet transmission is believed to be greatest at a distance of less than 3 feet from an infected person. For this reason, appropriate PPE precautions for patients with droplet-transmitted infections include keeping patients separated at least 3 feet from neighbors and wearing a mask for all close patient contact.

Microorganisms commonly transmitted via droplets include influenza and other respiratory viruses, group A streptococcus, and *Neisseria meningitidis.*[80]

Influenza virus types A and B cause respiratory illness in humans, ranging from mild to severe disease (influenza A infection generally causes more severe disease). Subtypes of influenza A virus are named for the surface antigens they display: H (hemagglutinin) and N (neuraminidase). Because these surface antigens change over time (termed antigenic drift), protective immunity from prior exposure to the influenza virus is partially lost. More infrequently, the surface antigens can change significantly (antigenic shift) and cause pandemic disease because the population has no immunity against the new virus strain. A pandemic H1N1 influenza A strain in 2009 caused illness in an estimated 60 million Americans.[106]

Because influenza virus subtypes change yearly, the CDC recommends that all persons older than 6 months be vaccinated yearly.[107] The influenza vaccine cannot cause influenza infection.[107] Anesthesiologists are at particular risk for exposure to influenza because of close contact with nasopharyngeal secretions. Increasingly, health care organizations are making yearly flu vaccination a mandatory condition of medical credentialing.[108]

Pertussis, a respiratory illness caused by *Bordetella pertussis*, and invasive meningococcal infections caused by *N. meningitidis* are two droplet-transmitted infections for which PEP is recommended for exposed health care workers.[80,105] Because intubation and suctioning are considered high-risk exposures to these infections, even vaccinated anesthesiologists should be aware of the need for chemoprophylaxis if they are involved in the care of infected patients.[24] The CDC recommends 5 to 7 days of macrolide therapy for pertussis exposure and single-dose oral ciprofloxacin or intramuscular ceftriaxone for exposure to invasive meningococcal disease.[109,110]

Droplet transmission of oral flora from health care workers to patients during lumbar puncture where the provider was not wearing a face mask has been implicated as a cause of bacterial meningitis.[80,111-113] Anesthesia providers should wear face masks when placing invasive catheters or needles, including into the spinal, epidural, or central venous spaces to reduce the risk of droplet transmission of infectious agents.

Airborne Transmission

Airborne transmission occurs when infectious particles are carried in the air and remain infective over time and distance, such as when infected droplets dry into much smaller particles called droplet nuclei or when small infectious particles (i.e., spores) are created. These small (<5 µm particles) are more likely to travel into the lower respiratory tract and cause severe infection. Patients with suspected airborne infections should be placed in a negative pressure rooms with specific air filtration requirements. All health care workers taking care of patients on airborne precautions should wear N95 or higher-level respirators.[80,87] These respirators must filter particles of 0.3 µm or greater in size with at least 95% efficiency. A tight mask fit is essential to proper mask function, and for this reason employers are required to perform respirator mask fit testing during employee training and periodically thereafter.[88]

Microorganisms transmitted via the airborne route include *Mycobacterium tuberculosis (TB)*, rubeola virus (causing measles), and varicella-zoster virus (causing chicken pox).[80]

TB is the result of infection with *M. tuberculosis*, an acid-fast bacillus that has caused disease in humans for more than 4000 years. Infection with *M. tuberculosis* occurs when a person inhales small infected airborne particles containing the bacterium. These particles, called droplet nuclei, are 1 to 5 µm in size and can remain airborne for prolonged periods, spreading throughout a room or building.[88] The risk of infection with *M. tuberculosis* varies with proximity to a source and duration of exposure. Anesthesiologists are at particularly high risk for TB exposure because bronchoscopy and endotracheal intubation have been reported as the two highest-risk procedures leading to skin test conversion in health sector workers.[89,114]

In otherwise healthy individuals who have been infected with *M. tuberculosis*, the disease is usually contained by the immune system in 2 to 12 weeks, when immunologic tests for TB will become positive,[88] although the bacteria can remain in the body for years, a condition referred to as latent TB. Latent TB is asymptomatic and is not infectious. Five to 10% of people who are infected with *M. tuberculosis* go on to develop active TB over the course of their lifetime.[115] The risk of developing active TB after infection with *M. tuberculosis* is much higher in those with a compromised immune system, such as persons with HIV or diabetes or undergoing immunosuppressive therapy.[88] Although most TB is curable if properly treated, untreated TB can lead to death in more than 50% of cases within 5 years.[35] Currently, the World Health Organization estimates that 1.7 billion people, approximately one-fourth of the world's population, are infected with *M. tuberculosis*.[115] Ninety-five percent of TB cases and deaths occur in developing countries.

In the United States, there were 9287 new cases of TB reported in 2016, with an incidence of 2.9 cases per 100,000 persons.[116] The incidence of TB in the United States has been declining after a surge in the 1990s, related to infection control measures put in place by the CDC.[88] All health care settings must have a TB infection-control program to identify and treat persons with TB, educate and screen health care workers at risk for contracting TB, develop environmental controls such as isolation rooms and negative pressure ventilation systems, and implement respiratory protection programs to reduce health care worker exposure risk.[88]

The commonly used tuberculin skin test (purified protein derivative) provides a qualitative measure of TB exposure. A newer quantitative test for TB is available that can test for atypical organisms but requires a blood sample.[88] All health care workers at high risk for exposure to TB should be skin tested at the time of employment and retested annually for a new exposure. A two-step test is recommended for anyone who tests negative more than 1 year after a prior test or TB exposure because latent TB infections can result in initial false-negative results from waning of the delayed type hypersensitivity response. The first test will "boost" the response, leading to a positive result with the second test in those with a true exposure.[88]

Health care workers who have a newly positive tuberculin skin test need to be screened for active TB with a clinical evaluation and a chest radiograph. If active TB is diagnosed, treatment according to recommended guidelines should begin immediately. Disease reporting laws generally require notification of local or state health departments within 24 hours of an active TB diagnosis. If active disease is excluded, drug therapy for latent TB infection is recommended for health care workers, in consultation with occupational health and infectious disease physicians. Standard drug regimens for treatment of latent TB are 6 to 9 months of isoniazid or 4 months of rifampin.[88] Those with a previous history of liver injury may not be good candidates for treatment of latent TB infection. Latent TB is not infectious, even if untreated, and should not preclude the anesthesiologist from engaging in patient care.

Complex Transmission

Microorganisms are commonly transmitted by more than just one route. For example, respiratory syncytial virus is most commonly transmitted via contact but can also be transmitted via droplets,[80,117] necessitating health care workers to use PPE to guard against both forms of transmission. Therapies commonly used for respiratory support, such as noninvasive positive pressure ventilation, have been implicated in the aerosol dispersion of respiratory diseases such as influenza.

Aerosol dispersion of infectious particles normally transmitted via droplet or contact transmission was a hallmark of the severe acute respiratory syndrome (SARS) viral outbreak that occurred between 2003 and 2004. SARS was a respiratory disease with a reported 6% mortality rate.[80] In some centers, up to 50% of the cases of SARS were in health care workers who had cared for patients with SARS.[25] Endotracheal intubation, tracheal suctioning, and care for patients on noninvasive positive pressure ventilation were identified as risk factors for health care worker infection.[80,105,118]

TABLE 88.5 Bloodborne Pathogens

	Risk of Seroconversion After Percutaneous Exposure*	Progression to Chronic Disease
Hepatitis B	6-30%**	5% of immunocompetent adults
Hepatitis C	0.5-2%	75-85%
HIV	0.3%	100%

*Risk varies depending on type of exposure and infectivity of the host.
**In those without serologic immunity.
Risks of seroconversion are related to: depth of exposure, viral load of patient, type of exposure (hollow-bore needle highest risk), presence of visible blood on the needle.

Bloodborne Organisms

Anesthesiologists are at constant risk of needlestick or other sharps injuries or injuries where blood or other serum-derived fluids from a patient could come in contact with nonintact skin or mucosal surfaces. The risk that accidental exposure to blood or body fluids will result in infectious transmission varies with the type of exposure (percutaneous being the highest risk), the instrument of exposure (hollow bore needles are higher risk than suture needles), the depth of needle penetration, the infectious agent, and the quantity of infectious particles a health care worker is exposed to. After an occupational exposure, the area should be washed with soap and water. Use of antiseptics or attempting to express fluid from the wound site has not been shown to be effective at reducing the rate of infectious transmission.[119] PEP may be recommended to reduce the risk of seroconversion. HBV, hepatitis C virus (HCV), and HIV are the three bloodborne infectious agents that pose the greatest occupational risk to the anesthesiologist (Table 88.5).[85]

HBV is a cause of acute viral hepatitis that is acquired by percutaneous or mucosal contact with infected blood or body fluids. Importantly, HBV can survive outside of the body for up to 7 days, and even needles without any visible blood can be infectious.[119,120] In unvaccinated individuals, the risk of seroconversion after percutaneous exposure to HBV varies from 6% to 30%, depending on the infectivity of the source and the type of contact with serum.[121,122] More than 50% of acute infections are asymptomatic, but signs of acute infection include fever, jaundice, fatigue, and abdominal pain. Rarely, acute HBV infection can lead to fulminant hepatitis. In adults, the virus is cleared completely after initial infection in up to 95% of cases.[120] However, chronic HBV can cause cirrhosis and hepatocellular carcinoma. Liver disease is the cause of death in 25% of those chronically infected with HBV.[120]

In the United States, there are approximately 20,000 new cases of HBV infection per year and an estimated 850,000 to 2.2 million people living with chronic hepatitis B infection.[123] Globally, there are nearly 900,000 HBV-related deaths every year. Before the introduction of a hepatitis B vaccine in the 1980s, HBV was a significant occupational hazard for anesthesiologists. One multicenter study of anesthesia residents in the 1980s found that 17.8% of 267 tested residents showed serologic evidence of exposure to HBV.[124] The availability of a vaccine has dramatically changed the epidemiology and occupational risk of HBV. The number of HBV infections in health care workers declined by 98% between 1982 and 2010.[119]

Health care workers are strongly encouraged to complete a series of three injections of hepatitis B vaccine. OSHA requires that health care facilities provide the vaccine free of cost.[125] Those who refuse hepatitis B vaccination must sign a statement declining the vaccine. Because immunity can wane over time and some people do not respond completely to the series, serologic testing for anti–hepatitis B surface antigen after vaccination and revaccination if immunity is not present may be part of an occupational health strategy at many hospitals.[119]

In the case of an accidental exposure, the source patient, if known, should be tested for HBV, in accordance with laws regarding informed consent. In those health care workers who have had a three-dose vaccine series and who have documented immunity by serologic testing, there is no need to test the source patient for HBV and no postexposure management is necessary.[119] If the health care worker does not have evidence of serologic immunity, the worker should be tested for immunity. In those without immunity and those who have not been vaccinated, hepatitis B immune globulin (HBIG) can be administered as PEP, together with the hepatitis B vaccine, if indicated.[119] HBIG will provide temporary protection from HBV for 3 to 6 months.[119]

HCV, like HBV, is a bloodborne virus that causes acute viral hepatitis. However, unlike HBV, HCV is not transmitted efficiently through percutaneous exposure to infected blood. The incidence of seroconversion after accidental percutaneous exposure to HCV varies but is estimated to be between 0.5% and 2%.[126] Of those who are exposed to HCV and develop acute infection, the infection is cleared in only 15% to 25% of cases.[126] The majority of infections progress to a chronic stage, and 5% to 20% of infections cause cirrhosis over the long term.[126]

In the United States, there were 2967 cases of acute HCV reported in 2016. Three to 4 million people in the United States have chronic HCV.[123] Unfortunately, there is no vaccine or PEP available for HCV, but there are effective treatments, including direct-acting antiviral agents, which can lead to complete clearance of infection in more than 90% of patients who are treated.[127]

Because HCV is treatable, health care workers who have an accidental exposure to HCV should be tested for anti-HCV within 48 hours of an exposure. All those tested without evidence of prior exposure should have repeat HCV RNA testing 3 weeks or greater from the time of initial exposure. If there is evidence of HCV infection, the health care worker should be referred for expert monitoring and treatment, if the primary infection is not cleared.

Accessing multidose vials for multiple patients, particularly propofol vials, has been linked to the transmission of HBV and HCV in many health care–associated outbreaks. In a 2006 high-profile case, five cases of HBV and six cases of HCV were linked to a single anesthesiologist at an endoscopy center, who was found to have used a syringe that had been in contact with a chronically infected patient to access a multiuse propofol vial, contaminating it.[128] Subsequent use of the propofol vial in other patients resulted in the transmission of HBV and HCV. Safe injection practices are part of standard infection precautions. The CDC recommends that vials should never be entered with a used syringe, even with a new needle or cannula. Medication vials in the immediate patient treatment area should always be single use.[80,85]

HIV is an RNA retrovirus that is spread through blood or serum-derived fluid. Once introduced into a host, HIV binds to cells with a CD4+ surface antigen (such as helper T lymphocytes) and replicates by integrating its viral DNA into the host cell DNA to establish a persistent infection.[129] According to statistics from the Joint United Nations Program on HIV/AIDS, in 2016 there were approximately 36.7 million people with HIV, with the most affected region being sub-Saharan Africa. HIV is mostly transmitted from person to person through unprotected anal or vaginal intercourse. HIV can also be transmitted from mother to child or through sharing or accidental exposure to an HIV contaminated needle.

If a health care worker has a percutaneous exposure to HIV, the risk of infectious transmission is low, approximately 0.3%. The risk of transmission after mucous membrane exposure (such as being splashed in the eyes or mouth with infected blood) is even lower (approximately 0.09%).[130] Injuries from patients with higher viral loads, use of hollow-bore needles, and deeper injuries are more likely to lead to HIV transmission.

The acute phase of HIV infection follows 3 to 6 weeks after exposure, with a nonspecific, febrile viral syndrome similar to influenza infection or mononucleosis that lasts 2 to 6 weeks.[129] The infection then enters an asymptomatic phase that can last for many years before the appearance of signs of immunodeficiency. Antibody screening tests for HIV will be positive in most patients by 8 weeks after the initial infection.[129]

After a high-risk exposure to an HIV-infected patient, health care workers should immediately contact their onsite occupational health department for postexposure management. The Clinician Consultation Center PEPline service offers free clinician advice on the risk of disease transmission and initiation of PEP.[130] Following an accidental occupational exposure, the source patient should be tested for HIV status with a rapid HIV test, observing local regulations regarding consent for HIV testing. Rapid HIV tests are considered sensitive and specific enough by the CDC to determine the need for PEP without additional testing.[131]

PEP with antiretroviral drugs is available and is most effective when given as soon as possible after the exposure, usually within 72 hours.[50] The decision to use PEP is nuanced and is based on the likelihood of exposure (i.e., if the source is known to have HIV, PEP is more strongly recommended versus if the source has an unknown status or the exposure was from an unknown source such as a sharps box). PEP can always be started and then discontinued after more information is obtained or expert consultation is available. A full course of PEP most commonly consists of a 28-day, three-drug antiretroviral regimen of tenofovir, emtricitabine, and raltegravir or dolutegravir. The most common side effect of

PEP is gastrointestinal upset, with fatigue, headache, and insomnia also contributing to poor PEP adherence. Tenofovir can cause renal toxicity and is relatively contraindicated in those with impaired renal function.

Regardless of whether PEP is initiated, the CDC recommends reevaluating exposed health care workers within 72 hours and, at a minimum, follow-up HIV testing of the exposed health care worker at 6 weeks, 12 weeks, and 6 months after exposure.[131] A systematic review of PEP found that the risk of HIV infection was 89% lower among animals receiving PEP after an exposure to HIV than those who did not receive PEP.[132] One small retrospective study of the use of zidovudine alone for PEP in health care workers exposed to HIV showed that the use of PEP resulted in a risk reduction of 81% for HIV seroconversion.[133]

Emerging Diseases

Occasionally, novel or previously nonvirulent infectious agents shift or become more pathogenic, creating anxiety and uncertainty among the public and the health care sector. In the presence of such outbreaks, medical centers must have plans and procedures in place to contain infectious agents, educate workers, and protect them from infection.

Prion diseases, caused by abnormal pathogenic agents able to induce misfolding of normal cellular proteins in the brain, lead to an incurable progressive neurodegenerative disease that usually results in death within 1 year of symptom onset. Creutzfeldt-Jakob disease (CJD), which caused approximately 500 deaths in the United States in 2016, is sporadic or familial in 95% of cases.[134] However, there have been occurrences of iatrogenic transmission of CJD through human-derived growth hormone, dural and corneal grafts, and the use of contaminated neurosurgical equipment.[80] Fortunately, since the implementation of routine sterilization practices, there have been no equipment-related cases[135] and, in the United States, no cases have been linked to percutaneous exposure or bloodborne transmission.[80] Variant CJD (vCJD) is a separate degenerative disorder caused by the same agent responsible for bovine spongiform encephalopathy (mad cow disease) in cows. vCJD transmission has largely been linked to the ingestion of contaminated meat in the United Kingdom; however, there were two reported cases of bloodborne transmission of vCJD.[80] SP should be used when caring for patients with suspected or confirmed prion disease. There are special guidelines for the reprocessing of surgical equipment used in patients with prion disease available through the World Health Organization.

Ebola is one of a group of viruses, including Marburg, Lassa, dengue, and yellow fever, that causes viral hemorrhagic fever syndromes.[80] Between 2014 and 2016, and again in 2018, in West Africa there were outbreaks of Ebola virus disease (EVD), with at least 28,652 cases of Ebola and 11,325 suspected deaths.[135a] EVD is transmitted readily to health care workers and is acquired through direct contact (through broken skin or mucus membranes such as the eyes, nose, or mouth) with blood or body fluids from an infected person but not via aerosol droplets.[80] The CDC recommends that all health care workers caring for patients with EVD use an N95 mask or higher respirator in addition to full contact and droplet precautions, to prevent accidental exposure of a mucus membrane to contaminated body fluid. Health care workers caring for patients with viral hemorrhagic fevers should go through special training on donning and doffing PPE, supervised by a trained observer to ensure that equipment is safely removed without contaminating the surrounding area.

Substance Use Disorders

Medical personnel treat patients suffering from substance use disorders (SUDs) every day. The psychiatric and social impacts are evident. Associated medical conditions such as HCV, HIV, bacteremia, and endocarditis require the highest level of care. Health care workers are not spared from this family of diseases. The Accreditation Council for Graduate Medical Education (ACGME) Common Program Requirements state that residents in anesthesiology understand their role in the recognition of impairment; however, recent work by Warner and associates has demonstrated that the problem may in fact be increasing and that the lives of promising young physicians are lost every year due to the use of drugs.[136,137] Some of the factors thought to lead to SUDs in health care personnel include access to potent substances, exposure to a high stress environment, long hours, variable shifts, and a culture of self-medication. Detection of SUDs is difficult because work may be the last area to suffer. Self-policing has been the main mode of detection, but organizations are currently incorporating more objective measures such as surveillance of medical records and drug testing. Timely and compassionate intervention is critical when an individual is suspected of performing under conditions of impairment, especially with SUDs, which threatens the safety of the resident, as well as that of the patient. Comprehensive treatment is critical for those diagnosed with an SUD.

EPIDEMIOLOGY

The incidence of SUDs including alcohol abuse among anesthesia personnel is the same as that in the general population, 10% to 20%. The incidence of misuse, abuse, or dependence on drugs other than alcohol among anesthesiologists has remained consistent over the years, at 1% to 2%.[138-141] A survey of Canadian residency program directors revealed a similar rate among residents, at 1.6%.[142] Bell and associates surveyed 2500 practicing nurse anesthetists and reported an incidence of 9.8%.[143] A lower rate was reported for fellows (0.4%). The problem of SUDs among anesthesia personnel is not limited to the United States, because studies in Australia, New Zealand, and Brazil[144] document similar results.[145-147]

The most common substance misused by anesthesia personnel has traditionally been opioids, as indicated in multiple studies (Table 88.6).[137-140,145-147] Over the past several years there has been an increase in the abuse of other drugs, including propofol, ketamine, and remifentanil, as well as volatile anesthetics.[148]

Since its introduction in 1986, the incidence of propofol abuse appears to be increasing. In a 2007 survey of 126 academic anesthesiology training programs, Wischmeyer and associates[149] reviewed 25 cases of propofol abuse and determined an incidence of 0.1% per decade, a fivefold increase from a previous study by Booth et al.[140]

TABLE 88.6 Most Common Drugs of Abuse

Study (Year)	Cohort (Years)	Most Used Substances
Ward (1980)	289 anesthesiology programs in United States 1970-1980	Meperidine Fentanyl Morphine Diazepam Other Alcohol
Menk (1990)	159 anesthesiology programs in United States 1975-1989	Parenteral opioids Diazepam Alcohol Inhalational agents
Weeks (1993)	Anesthesiology training programs in Australia and New Zealand 1981-1991	Opioids Cannabis Cocaine Alcohol Benzodiazepines Barbiturates
Bell (1999)	2500 Actively practicing certified registered nurse anesthetists in United States 1999	Benzodiazepines Propofol Inhalational agents Opioids Dissociative drugs (ketamine)
Booth (2002)	Academic anesthesiology programs July 1990-July 1996 (residents) July 1990-June 1997 (staff)	Fentanyl Sufantanil Cocaine Nitrous oxide Meperidine Midazolam Diazepam Ketamine Halothane Propofol Others
Fry (2005)	Anesthetists in Australia and New Zealand (128 anesthesiology departments) 1994-2003	Opioids Induction agents Benzodiazepines Alcohol Inhalational agents
Palhares-Alves (2012)	Anesthesiologists treated in a reference program in Brazil 2002-2009	Opioids Benzodiazepines Alcohol Marijuana Amphetamines Cocaine/Crack
Warner (2013)	Anesthesiology training records from ABA, DANS, NDI 1975-2010	Opioids Alcohol Marijuana/Cocaine Benzodiazepines Propofol
Fry (2015)	Australian and New Zealand anesthesia trainees 1981-2013	Opioids Propofol Benzodiazepines Alcohol Recreational drugs

(Table, Study Characteristics) Modified from Zuleta-Alarcon, A, Coffman JC, Soghomonyan S, et al. Non-opioid anesthetic drug abuse among anesthesia care providers: a narrative view. *Can J Anesth/J Can Anesth*. 2017;64:169–184.

The incidence of death was 28%. Health care providers that abuse propofol tend to be female, have training as an anesthesiologist or nurse anesthetist, and work in the operating room theater.[150] Propofol abuse tends to present early in dramatic fashion such as a motor vehicle accident or other physical injury in the setting of acute intoxication.

Ketamine may make up approximately 2% to 4% of abused substances.[137,139] Ketamine causes hallucinations as well as calming effects.[148,151] The risk of death associated with ketamine may be less than opioids among impaired providers, but the acute impact of delusions, delirium, and confusion have the potential to result in injury. Long-term effects include memory impairment, attention dysfunction, tolerance, and flashbacks.

Inhalational anesthetic drug abuse comprises approximately 2% to 5% of misused substances among anesthesia providers.[137,139,146,148] A 2008 survey demonstrated that 22% of anesthesia training programs had at least one provider who had been impaired by inhalational anesthetics and that 26% of those died.[152] N_2O was the most commonly abused drug, followed by volatile anesthetics. Only 22% of those individuals who abused such anesthetics were ultimately able to return to work. The report noted that only 7% of the anesthesia departments had any pharmacy accounting for inhalational anesthetics.

Anesthesia providers may misuse benzodiazepines to relieve stress and to treat insomnia.[148] Benzodiazepines are the drug of choice for 5% to 15% of anesthesiologists impaired by SUD and are the drug of choice of impaired SRNAs.[137,139,143,145,146] Remifentanil was introduced in 1997 as an opioid with a rapid onset and rapid rate of degradation. Remifentanil does have typical opiate-like effects, but when compared with fentanyl, its significantly shorter duration of activity makes it less likely to be abused than fentanyl. Baylon et al. noted that remifentanil is unlikely to be used “on the street,” but if access to the medication and infusion pumps increases and addicts recognize minimal observable effects, abuse of the medication may increase.[153] Remifentanil abuse has been reportedly used by a resident as a foray into opioid abuse.[154]

ETIOLOGY

The underlying etiology of SUDs among anesthesia providers, who are presumably more intimately aware of the risks, remains undetermined. No study has clearly identified individual factors, and those often cited are not specific to the practice of anesthesiology. Risk factors for SUDs may be biologic, psychological, or occupational.[155]

Hiroi and Agatsuma surmise that certain individuals are more likely to transition from substance use to dependence if they are genetically susceptible based upon animal studies.[156]

A family history of SUDs has also been identified as a risk for relapse among addicted individuals.[157] Individuals receiving medical education within the United States had higher rates than those from other countries.[158]

Personality may play a role in the likelihood of developing SUD. Trinkoff and Storr studied the incidence of SUD among nurses and noted that those in emergency medicine and critical care had higher rates than other nursing specialties.[159] These areas of practice are like those in which anesthesiologists work.

Anesthesiologists directly obtain and administer medications to patients. A review of anesthesiologists treated for SUDs by the Medical Association of Georgia Impaired Physician Program concluded that 85% of residents in the program selected anesthesiology because of access to medications and drugs.[160] Emergency and critical care nurses,[159] and pharmacists also have access to medications and have high rates of SUDs.[161]

Anesthesiologists, like other physicians, often self-medicate rather than seeking appropriate medical care from their physician. Christie and colleagues reported in 1998 that more than 50% of prescription medications used by trainees were self-prescribed.[162] Unpredictable schedules, ease of access to medications, and knowledge of medical conditions were cited as potential causes of this behavior,[162] as may the lack of access to health care providers.[162,163] Fortunately, a study showed that the incidence of self-medication may be decreasing.[164]

IMPACT

Health care providers who suffer from SUDs generally divert their drugs from the health care facility at which they work. The National Association of Drug Diversion Investigators defines drug diversion as “any criminal act or deviation that removes a prescription drug from its intended path from the manufacturer to the patient. This can include the outright theft of the drugs, or it can take the form of a variety of deceptions such as doctor shopping, forged prescriptions, counterfeit drugs, and internal smuggling.”[165]

SUDs in health care providers affect their well-being, their career, and their family. Individuals with SUDs have high rates of divorce and marital discord. The cost of rehabilitation and follow-up care is significant. Problems with medical licensing are common. In addition, the individual with an SUD in a sensitive position may carry the stigmata of impairment. The death rate for anesthesiologists with SUDs is 9% to 15%.[138,139,158]

It is generally believed that the impact of SUD is largely limited to the individual with the disease, but an increasing number of reports of injury to patients is being published. Shaefer and Perz reported on public outbreaks of communicable diseases such as HCV, HBV, and other organisms in hospital settings where health care providers abusing drugs placed patients at risk.[166] These situations arose because of providers diverting drugs from the work environment for their own use.

PREVENTION AND DETECTION

Prevention of SUDs among health care providers has been largely limited to education on the impact of drug use. These efforts may include presentation of videos demonstrating the death of a promising young resident physician and the impact on his family. Individuals with a history of SUDs are often invited to share their stories of drug use, detection, and recovery. Members of the state Physicians Health Services are often invited to present resources to

TABLE 88.7 Behaviors and Indicators that Could Indicate Substance Use Disorder

Potential Indicators at Work	Potential Indicators at Home	Physical
Changes in behavior (wide mood swings, anger, euphoria, gossip by others)	Withdrawal from family and friends	Pinpoint pupils
Progressive increases in narcotic use for anesthetic management	Changes in behavior, mood swings, anger	Diaphoresis, tremors
Recurrent documentation errors related to medications	Frequent, unexplained illness	Odor of alcohol on breath
Preference for working alone	Risk behaviors—gambling, extramarital affairs	Weight loss
Frequent requests for bathroom breaks	Decrease in sexual drive	Wearing of long-sleeved gowns (to hide needle tracks or prevent withdrawal chills)
Unusual willingness to provide breaks for others or work additional shifts/calls	Finding of drugs and syringes at home	
Frequent appearances in hospital when not on call	Increased use of alcohol	
Falling asleep during rounds, in OR	Increase interactions with individuals who use illicit substances	
Unexplained absences		
Difficulty contacting when on call		
Excessive postoperative pain in patients		
Direct observation of use		
Sudden death		

OR, Operating Room

support physicians. Lutsky et al. reported that in 1993, only 15% of anesthesiologists could report receiving any education on impairment during their residency.[167] Booth and colleagues reported that, despite enhanced education over the course of their study, the incidence of SUDs had not decreased.[140]

Detection of SUDs has traditionally relied upon colleagues observing and reporting performance characteristics that could indicate SUDs (Table 88.7). However, many health care professionals will not report or even seek assistance for colleagues who may be impaired. In an investigation of reporting behaviors, only 64% of physicians agreed with the statement, "Physicians should report all instances of significantly impaired or incompetent colleagues to their professional society, hospital, clinic and/or relevant authority."[168] Multiple reasons for not being willing to report were cited, including the perception that it is not one's responsibility to report or a fear of retribution for reporting. Because reliance on observation by colleagues and reporting has proven unreliable and death is too often the initial presenting factor for SUD, institutions are starting to use new measures, including anesthesia record surveillance, vigorous control and testing of returned substances, and drug testing of providers.

Medical record surveillance is the practice of comparing the anesthetic record to the medications that have been dispensed for patient use. Pharmacists or other healthcare personnel manually review the record and compare documentation with the amount of medication returned. Inconsistencies may indicate medication diversion from the patient. Discrepancies in practice patterns may also be detected by record surveillance. Epstein and colleagues retrospectively reviewed medical records through a commercial drug-dispensing system to evaluate discrepancies that could indicate diversion.[169] Factors such as high use of opiates, excessive medication wastage, and late transactions on canceled cases were not indicative of diversion, whereas transactions late in the day after completion of cases and transactions that occurred at locations different from where the procedure occurred were associated with episodes of diversion. These authors posited that a surveillance scheme used in real time might identify episodes of diversion earlier than traditional behavioral observation and reporting methods, an assertion they later validated prospectively.[170]

Most organizations use the practice of witnessed wasting of controlled substances. Such practice involves a second individual observing and documenting that controlled substances remaining after a case are wasted. This system relies upon the integrity of several steps: that the elimination of the entire substance occurs, that both providers are honest, and that the wasted substance is a controlled substance at the appropriate concentration. Leaders at the Mayo Clinic recognized these potential weaknesses and developed a vigorous system to prevent diversion. The system requires that all unused substances are returned to a secure, locked box. The box is returned to the pharmacy, where the amount returned is reconciled with the dispensing record and anesthesia record. Random samples are periodically sent for toxicologic analysis. This process occurs under video surveillance to prevent diversion by the pharmacy department.[141] This system has successfully identified multiple health care providers and other personnel diverting substances.

Two major events resulted in widespread use of urine drug screening to reduce the incidence of SUDs. During an investigation after an aircraft accident aboard the USS Nimitz in the early 1980s, it was discovered that nearly 50% of the ground crew tested positive for illicit substances.[171] In addition, the passage of the Drug-Free Workplace Act of 1988 required that all federal contractors and all federal grantees establish drug-free workplaces to receive a grant of contract from the U.S. government.[172] The act included the provision that individuals in safety-sensitive professions could be subject to drug testing. The Department of Anesthesia, Critical Care, and Pain Medicine of the Massachusetts General Hospital (MGH) first reported the feasibility of drug testing in anesthesiologists 2008.[173] The incidence of SUDs prior to implementation of testing was 1% among all residents and 2.2% among first-year residents. There were no cases of SUDs reported within the first 4 years of implementation of the program, although the results were not statistically significant. In 2010 Tetzlaff and associates reported their experience developing an SUD prevention program at the Cleveland Clinic's Anesthesiology Institute.[174] The clinic implemented a comprehensive substance abuse prevention protocol that included randomized urine toxicology screening and "for cause" testing that would be initiated in the event of a significant decline in performance. Assessment of the prevention program is ongoing.

Implementation of a drug-testing program is not without challenges and concerns. Senior physicians may opine that their years without a problem indicate that they are without risk and should not be subject to an invasive test without cause. Although Alexander and colleagues reported that the highest rate of SUDs among anesthesiologists occurred within the first 5 years after medical school, the risk is never eliminated and extends into the senior years of one's career.[175] Some argue that if drug testing is not a condition on a contract than it cannot be required. Initially, participation in the MGH drug-testing program was voluntary, but testing became mandatory for all physician members in 2005.

False-positive results are a legitimate concern for those tested, as well as for those administering the program. For example, one of two false-positive tests at MGH was likely due to the consumption of the poppy seeds in a bagel eaten the morning of testing. It was found that the testing threshold for morphine (300 ng/dL) was set far lower than the federal level of 2000 ng/dL.[176] In the second event, the initial enzyme-linked immunosorbent assay reported the presence of ketamine, whereas confirmatory gas chromatography/mass spectroscopy reported a result that was indeterminant. Policy dictates that a second sample is collected at the original test. This second sample was sent to another certified laboratory where a "negative" result was found.[176] Some test results may be positive due to legitimate medication use for which an individual has a valid prescription. A certified, unbiased Medical Review Officer trained to the standards of the Department of Health and Human Services Substance Abuse and Mental Health Services Administration Center for Substance Abuse Prevention should review all results.[177]

INTERVENTION, TREATMENT, PROGNOSIS, AND REENTRY

SUDs curtail promising careers and claim the lives of anesthesiologists every year.[175] Studies have shown that death is the initial presentation in 9% to 16% of cases.[138,139,178] Residents who have an SUD during their training have a markedly increased risk of death after training compared with their colleagues without an SUD.[141]

When an SUD is identified or suspected, it is critical that concerned and compassionate colleagues intervene to prevent injury or harm to patients and to help the impaired individual. An organized, structured, and supportive plan to present the concerns to the impaired individual is critical. Such an "intervention" is more likely to maintain the confidence of the individual than a "confrontation" where the individual feels that guilt is presumed.[179] A suggested approach used at MGH is that a consistent team including the director of the SUD prevention program, another department leader, and a designated psychiatrist familiar with SUDs and the department's policy should be involved in all interventions. Other individuals such as a mentor or certified registered nurse anesthetist (CRNA) leader may be included when appropriate. The intervention team discusses each case before meeting with the individual. The individual is removed from clinical duty in a confidential manner. The issues of concern are presented in a supportive and nonconfrontational manner. If additional drug testing is indicated, the individual is escorted for testing. In the case of admitted or demonstrated SUD, treatment is required. Should an individual refuse to seek care, an immediate report to the Board of Registration in Medicine is made. When it is uncertain whether an SUD is the cause of impaired performance, a medical leave of absence is granted pending completion of evaluation and testing. In either circumstance, access to controlled substances and the operating room is restricted, pending outcome of an investigation.

It is critical that factors other than SUDs be considered, because the "impaired" anesthesiologist is not necessarily an "addicted" anesthesiologist.[180] Other issues that may lead to inadequate or unsafe performance may be depression, anxiety, financial difficulties, and family struggles, and other medical illness may manifest in similar ways to SUDs. Treatment and recovery after a diagnosis of an SUD is complicated for professionals whose livelihood involves daily exposure to the substances which they misuse. In a report by the California Physicians Diversion Program,[181] anesthesiologists made up 5% of the physicians in California yet 17.4% of those in the program. The recovery rate was 69%, with the majority reentering anesthesiology (96%). The relapse rate among those using opioids was 16%. Paris and Canavan studied anesthesiologists compared with physicians from other specialties.[182] The relapse rate was high (40.6%) but like other specialties, relapse was less likely when the individual entered another specialty. In a 5-year longitudinal study of physicians enrolled in physician health programs (PHPs) between 1995 and 2001, a subset of 102 anesthesiologists of the 904 physicians was independently analyzed.[183] Anesthesiologists primarily enrolled in the recovery programs due to opioid abuse, whereas alcohol was the most common drug of abuse for other physicians. Compared with other physicians, anesthesiologists had no higher rate of mortality, relapse, or disciplinary action during the period of recovery. The study's conclusions are limited because only 16 of the 48 PHPs elected to participate because of lack of resources or regulatory impediments to participation. Factors associated with increased risk of relapse specifically among physicians have not been studied well. Domino and colleagues reviewed risk factors for physicians in the Washington Physicians Health Program in 2005.[157] Among a cohort of 292 health professionals enrolled in the program, 74 had at least one relapse (25%). Those with a family history of SUD, as well as individuals whose drug of misuse was a major opioid and who had a coexisting psychiatric disorder, had higher risks of relapse. Individuals with all three risk factors—family history, a coexisting psychiatric illness, and abuse of a major opioid—had the highest relapse risk.

States, hospitals, and departments often rely on the help of PHPs to guide the recovery of physicians impaired by any condition, particularly SUDs. PHPs are not addiction programs, but they do provide active case management and guidance through the diagnosis, treatment, recovery, and reentry process. Individuals with SUDs are required to sign contracts with a PHP and agree to treatment (usually inpatient), follow-up, monitoring, and other stipulations during recovery. PHPs offer a temporary safe haven during the initial phases of management. PHPs work closely with state medical boards to ensure that a physician is compliant with requirements of a comprehensive recovery process.[184]

Specialists in the treatment of physicians with SUDs have identified six lessons that appear to promote long-term recovery through PHPs[185]: (1) Successful programs promote a zero-tolerance policy for any use of alcohol or other nonmedical drugs. (2) Evaluation of individuals should be complete, comprehensive, and patient-focused rather than merely repeating the same practices for every single patient. (3) Frequent random drug testing for both alcohol and drugs serves as a constant reminder of the obligation of the individual being treated. (4) PHPs use leverage with medical boards, hospitals, and medical groups, which may serve as a deterrent to relapse. (5) PHPs define what constitutes a relapse and act in a quick and certain way with meaningful consequences. (6) Lastly, those in recovery working through PHPs generally must be involved in 12-step programs such as Alcoholics Anonymous or Narcotics Anonymous.

The use of naltrexone may reduce the chance of relapse among anesthesiologists in recovery. The state of Florida mandates that anesthesiologists referred for opiate disorders are contractually required to use naltrexone for 2 years.[186] Naltrexone has side effects such as headache, fatigue, insomnia, anxiety, and nervousness, all conditions that can impair performance. In a small prospective study, 11 anesthesiologists treated with naltrexone were compared with 11 controls: only one individual in the naltrexone program relapsed while 8 of 11 (72%) in the untreated group relapsed. Those on naltrexone also had higher rates of return to the practice of anesthesiology.

Whether SUD residents in anesthesia are returned to their training programs or are retrained in either a different specialty or another career is even more controversial. In a review of outcomes for residents treated for chemical dependency, most program directors (80%) had at least one impaired trainee and 19% reported a pretreatment fatality.[187] A high percentage (92%) of trainees attempted reentry into anesthesiology, but only 46% ultimately completed training. The rate of death was 9%. A survey of anesthesiology residency training programs in 2007 showed that nearly two thirds of program directors had at least one resident who required treatment for SUDs.[188] The relapse rate after treatment was 29%, and death occurred in 10%. Despite these statistics, 43% believed that residents should be allowed to continue their training. Bryson and Levine conducted an intensive 12-month posttreatment program involving an anesthesia simulator followed by gradual reintroduction to the clinical practice of anesthesia.[189] Five residents participated in the program, and three (60%) successfully finished their training program. Two of those individuals remained in recovery at 3 and 6 years, whereas one relapsed at 9 years.

The decision whether to return or retrain is difficult, and circumstances vary on an individual basis. Residents often do not have the social and financial supports of graduated physicians, and they are exposed to the substances of risk for perhaps 40 more years. In addition, their youth may predispose them to denial of the disease.

SUDs among anesthesiologists remain a problem. Enhanced education and substance control measures should continue. Other efforts such as drug testing should be explored. When an individual is suspected or found to have an SUD, a timely, compassionate, and professional intervention is necessary to ensure the safety of the individual and patients.

Fatigue

Excessive tiredness due to inadequate sleep, physical illness, or other causes can result in fatigue. In general, physicians are not able to compensate for loss of sleep or to recover from illnesses because of the requirements of their work environment to patient care issues or work structures. Fatigue may place patients at risk of injury, as well as impact the health and safety of anesthesiologists. Fatigue in trainees became a public concern with a case involving Libby Zion, a young woman whose unfortunate death was determined in court to be related to 36-hour duty periods worked by the physicians providing her care. Physicians should understand the causes of fatigue, the impact on patients and themselves, and the means to manage the challenges ever present in a difficult and unpredictable work environment.

INCIDENCE AND IMPACT

Few studies of the impact of fatigue have been performed in the population of providers involved in anesthesia care. Gravenstein and colleagues conducted a survey of anesthesiologists, residents, and CRNAs wherein residents and CRNAs noted that they occasionally worked beyond what they would consider their limitations and that they had made errors associated with fatigue.[190] Ten years later, Cao and colleagues evaluated the differences in performance during day and night shifts among residents. Residents had a more negative mood at night, although workload ratings and alarm response times were no different between the two

TABLE 88.8 Accreditation Council for Graduate Medical Education Duty Hour Rules and Modifications

2003 ACGME Duty Hour Standards	2017 ACGME Clinical Experience and Education Modifications
80-h weekly limit (averaged over 4 weeks)	Clinical work done from home must be counted toward the 80-h weekly maximum
10 h between work shifts (suggested)	All residents must have at least 14 h free of clinical work after 24 h of clinical assignments
Limit of 24 h of continuous duty plus 6 for transition of care	Clinical work for all residents must not exceed 24 h of continuous schedule clinical assignments
One day in 7 free from all obligations	
In-house call no more than every 3 nights	
Options for some programs to request 8 h additional time	Clinical work exceptions may be granted by the RRC up to a maximum of 88 h based on sound educational rationale
	Residents who have handed off work have the flexibility to remain at work in unusual circumstances for the benefit of patient care. Hours must count towards the 80-h work week

ACGME, Accreditation Council for Graduate Medical Education; *RRC*, Residency Review Committee.

shifts.[191] More recently, Husby and colleagues studied the impact of short- and intermediate-duration hospital calls on anesthesiologists.[192] Reaction times were significantly worse after 18-hour shifts, but not after shorter shifts. The incidence of adverse events has been found to be higher later in the day; the lowest rate of adverse events was found at 9:00 AM, whereas the highest rate was at 4:00 PM.[193]

The impact of fatigue on the safety of the physicians themselves may be significant. Extended work duration of interns is associated with increases in percutaneous injuries.[194] A lapse in concentration and fatigue were the most commonly cited contributing factors. Injury was more common during the night shift than during the day. Depression, fatigue, and sleepiness were associated with a higher likelihood of a motor vehicle incident in resident physicians.[195] The personal lives and well-being of trainees may also be impacted by sleep loss and fatigue. A study of 149 resident-physicians at five academic medical centers revealed that many residents perceived that sleep loss and fatigue had a major impact on their personal lives such that personal and social activities were deferred or postponed.[196]

Attempts to restrict duty hours have been implemented by the ACGME. The benefit of limitation of duty hours is unclear, and negative consequences on patient care and education may result. Early studies of the impact of duty hour restrictions demonstrated that when efforts were made to reduce sleep deprivation, medical errors were lower, as were patient hospital length of stay and laboratory tests ordered,[197] but this has not been a consistent finding, and the relationship between duty hour restrictions and quality of care remains controversial.[198]

GUIDELINES

Training for resident physicians requires a balance between the safety of both patients and residents, as well as assurance that optimal educational outcomes are achieved. The ACGME implemented duty hour restrictions for trainees in 2003 and updated these restrictions in 2011. At their core, the restrictions included an 80-hour weekly duty limit, 10 hours of rest between shifts, and no more than 24 hours of continuous duty with a limit of 6 hours for transition of care and education.[199] Many potential benefits were anticipated including improvements in patient care, improved resident quality of life and health, and decreased risk of personal harm due to fatigue.[200] At the time of implementation of duty hour restrictions, many physicians anticipated several unintended consequences, including discontinuity of care, an increased work burden on attending physicians, negative impact on professionalism and the perceptions of the profession, poor preparation for the realities of independent practice, a reduction in educational opportunities, and a major economic impact (Table 88.8).

Multiple studies have been performed on the impact of these changes. Ahmed and associates performed a systematic review of the effects of duty hour restrictions in surgery.[201] There was no significant improvement in patient safety. Their review found that wellness improved, and fatigue and burnout declined after implementation of the 2003 guidelines but further improvements were not seen after the 2011 modifications. The effects on education and training were either a worsening or no change. Written examination scores were unchanged, but passage of oral examinations decreased in surgery.

REQUIREMENTS AND RECOMMENDATIONS

The ACGME Program Requirements for Graduate Medical Education in Anesthesiology require inclusion of formal efforts to educate faculty and residents in the recognition of fatigue, alertness management, and fatigue mitigation. Programs are also required to ensure adequate sleep facilities and safe transportation options after duty.[202] The Association of Professional Sleep Societies' Committee on Catastrophes, Sleep, and Public Policy developed a consensus report concluding that human performance is at its most vulnerable period between 1:00 AM and 8:00 AM, with a less pronounced period from 2:00 PM to 6:00 PM (Table 88.9).[203] It is also known that sleep duration less than 7 hours affects cognitive performance involving vigilance, attention, cognitive processing speed, and working memory, and at least 7 to 8 hours are recommended per night.[204] Less sleep and patterns associated with chronic sleep deprivation are associated with even more impairment. Recommendations are in Table 88.9.

Researchers at the Mayo Clinic studied whether capping residents' patient census would improve the perception of workload among residents.[205] These changes led to improvements in ratings of workload appropriateness and conference attendance. Duty hour violations were

TABLE 88.9 Recommendations of the Association of Professional Sleep Societies

Observation	Recommendation
The time of 1 AM-8 AM constitutes a time span when human medical and performance catastrophes are far more likely to occur A second but less pronounced period from 2 PM to 6 PM constitutes a second period of vulnerability	Increased awareness is necessary. Policymakers are urged to consider relevant aspects of sleep physiology that affect performance.
Inadequate sleep, even as little as 1-2 h, can greatly exaggerate the tendency for error during the time zones of vulnerability	Programs should be developed to identify the signs of sleep-related error in vehicle operation and on the job, particularly in industries that have a responsibility to minimize accidents and effort for the sake of public health and safety
	Industries and services impacting public safety should address the physiologic needs of workers
	Attention should be given to identification of the least adaptive shiftwork schedules and to the implementation of schedules that promote health and safety

Modified from Mitler MM, Carskadon MA, Czeisler CA, et al. Catastrophes, sleep, and public policy: consensus report. *Sleep*. 1988;11:100–109.

decreased, as were patient readmissions, but other safety outcomes, such as the rate of rapid response team and “code blue” events, were unchanged.

Acknowledgment

The editors, publisher, and Dr. Christopher Choukalas thank Dr. Theodora Nicholau for her contribution to this chapter in the prior edition of this work. It has served as the foundation for the current chapter.

89 Clinical Research

KATE LESLIE, COR J. KALKMAN, and DUMINDA N. WIJEYSUNDERA

KEY POINTS

- Clinical research describes the characteristics and mechanisms of disease and injury in humans and investigates drugs, devices, diagnostic products, and bundles of care with the aim of providing high-quality evidence to guide clinical practice that improves patients' lives.
- Investigators are constrained by the need to draw conclusions based on a sample of patients, providers, or systems rather than the whole of the population of interest, and this introduces random, systematic, and design error that threatens internal and external validity.
- Observational (or nonexperimental) studies involve allowing nature or clinical care to take its course, without any major modification due to study-related procedures. However, nonexperimental designs are prone to systematic error, such as selection and information bias.
- In experimental studies the investigators do not let nature (or clinical care) take its course, but actively intervene to test a new intervention. Randomization and blinding reduce the risk of random and systematic errors in experimental studies, but generalizability can be limited.
- Systematic reviews synthesize the medical literature using a transparent search strategy that every reader can replicate and update, and accompanying metaanalyses produce aggregate estimates of treatment effects.
- A carefully designed protocol is the foundation of all clinical research, facilitating the review, conduct, and eventual publication of the project. Prior planning of sample size and statistical analyses is essential.
- Appropriate ethics, registration, and regulatory approvals; financial, data, and human resource management; plans for monitoring patient safety and data integrity; and plans for publishing the results and sharing the data are vital to the proper conduct of clinical research.
- A quality improvement cycle of reflection, feedback, and forward planning is beneficial. Giving patients an opportunity to comment on the studies in which they participated gives researchers fresh insight and opens up new avenues of research.

> *The measure of greatness in a scientific idea is the extent to which it stimulates thought and opens up new lines of research.*

Introduction

Research is systematic investigation for the creation of generalizable knowledge. Clinical research describes the characteristics and mechanisms of disease and injury in humans, and investigates drugs, devices, diagnostic products, and bundles of care for human use. Clinical research also includes investigating the interactions of health professionals, students, and other stakeholders with the health care and health education systems. Most studies address an aspect of quality of care or education such as safety, effectiveness, patient-centeredness, timeliness, efficiency, and equity.[1]

Miller's Anesthesia includes references to tens of thousands of clinical research studies. The main purpose of this chapter is to describe how these studies were designed and conducted. The chapter connects directly with Chapter 91, which elaborates on how to interpret and use evidence for clinical decisionmaking. Other related chapters include Chapter 1, Chapter 2, Chapter 4, Chapter 5, Chapter 8, and Chapter 30. Our goal is to describe how clinical research originates and to inspire our readers to create and support the use of high-quality evidence that is essential in guiding clinical practice that focuses on improving patients' lives.

Key Principles

Researchers want to produce results that will be useful to clinicians in improving patients' lives. However, they are constrained by the need to draw conclusions based on a sample of patients rather than the population of interest as a whole.[2] The random, systematic, and design errors introduced by studying a sample affect the confidence with which the association found in the study can be claimed to truly represent the causal effects of the exposure on the outcome ("internal validity") and impair the generalizability of the results to the source population for the sample and the population of interest as a whole ("external validity").[3,4] These errors will be discussed briefly here and will be highlighted in subsequent sections of this chapter.

RANDOM ERROR

Random error (or "chance") in the association between an exposure and an outcome is introduced by variation between the individuals in the study and within individuals over time, and variation between and within measurements made during the study.[5,6] Random error is equally likely to cause false acceptance and false rejection of the null hypothesis (i.e., the hypothesis that there is no effect). The risk of drawing false conclusions increases with decreasing sample size and more statistical testing.

SYSTEMATIC ERROR

Systematic errors (or "biases") also threaten identification of the true causal effect that the exposure had on the outcome in the sample. They can arise from nature (confounding), selection features of the study (selection bias), or measurement features of the study (information bias). In contrast to random error, which distorts the results of a study in both directions, systematic error distorts only in one direction (i.e., toward acceptance *or* rejection of hypotheses).

Confounding

Confounding is a bias that arises when an association between an exposure and an outcome fails to take account of a third factor (a "confounder") that is associated with both the exposure and the outcome.[5,6] Confounders can be risk factors, preventive factors, or surrogate markers for another cause of the outcome, but they cannot be intermediary steps in the causal pathway between an exposure and an outcome. They may be known and measured ("known knowns"), known and unmeasured ("known unknowns"), or unknown and unmeasured ("unknown unknowns").[7] In observational studies, design (e.g., sampling restriction, matching) and analysis (e.g., statistical adjustment) options only address the distribution of measured confounders. Randomization distributes measured and unmeasured confounders evenly between groups (with increasing reliability in larger studies).[8] Concealment of allocation prevents selective recruitment, and blinding prevents confounding that results when knowledge of group allocation changes processes of care or behavior.[9]

The importance of confounding varies with the type of study. In studies focusing on causality (e.g., whether smoking causes lung cancer), investigators attempt to collect and manage all possible confounders, yet they must always take residual confounding into account or use randomization and blinding to ensure that known and unknown confounders are balanced between the groups. In studies focusing on prognosis (e.g., studies predicting the likelihood that a patient will survive the proposed surgical procedure) any variable that contributes to improved prediction can be used in the prediction model.[10]

Selection Bias

Bias can be introduced by the methods used to select a population of interest, to identify and sample a source of such patients, to recruit and retain those patients, and to disseminate the results.[4] Observational studies are prone to bias with respect to selection of sources of exposed and unexposed patients, or cases and controls. Patients and their treating team can introduce bias by participating or not participating based on the exposures and outcomes under study. Prospective cohort studies and randomized trials are prone to bias with respect to differential loss to follow-up.[2] Studies without preplanned and publicized protocols and statistical analysis plans are prone to bias with respect to selection of outcomes to report (favoring outcomes with statistically significant differences between groups), and studies that fail to find a difference between groups with respect to the primary outcome ("negative" studies) may result in "publication bias," that is, they are either never submitted or not selected for publication by journal editors.[11]

Information Bias

This type of bias can be introduced by inaccurate measurement or classification of exposures, outcomes, and other measured variables. This error arises when survey instruments and diagnostic tests are invalid or unreliable and may be differential (affecting groups differently) or non-differential (affecting groups similarly).[2] Recall bias arises when recollection of past exposures is affected by whether the patient experienced the outcome or not. Socially desirable response bias arises when participants give answers based on their assumptions about the investigators and society. Patients who are not assessed for the primary outcome (i.e., whose information is "missing") can cause random or systematic error, and this should be assessed with sensitivity analyses.[12]

DESIGN ERROR

Design errors limit the usefulness of research to clinicians, even if the research is free of random and systematic errors, by affecting its generalizability.[3] Examples of such design errors include studying exposures that are expensive or difficult to implement; comparing new treatments with placebos or weak treatments rather than the best available option; assessing outcomes that are not relevant to patients and the community; and seeking to prove that a new treatment is superior to an old treatment, when proving that it is equivalent or non-inferior would be more useful.[3]

STATISTICAL INFERENCE

The *P*-value is the "probability under a specified statistical model that a statistical summary of the data (e.g., the sample mean difference between two compared groups) would be equal to or more extreme than its observed value."[13] For example, $P = .05$ means that under the null hypothesis there was a 5% chance of observing results at least as extreme as those seen in the study.[14] *P*-values can indicate how incompatible the data are with a specified statistical model, but do not measure the probability that the studied hypothesis is true nor that the data were produced by random error alone.[13] Confidence intervals are better suited to reflecting the size and precision of the treatment effect than *P*-values: the 95% confidence interval refers to the fact that if the same study were repeated many times and the confidence intervals were similarly calculated for each case, 95% of such intervals would include the true treatment effect.[14] The minimal clinically important difference is important when assessing confidence intervals. If the lower limit of the confidence interval excludes the minimal clinically important difference, then the effect of the treatment is likely to be important.[14] Bayesian inference overcomes some of the limitations of *P*-values and confidence intervals.[15] Instead of interpreting the frequency of a phenomenon, Bayesian

interference incorporates prior evidence, biological plausibility, and pre-existing beliefs into the calculation of the probability of a treatment effect.[14]

Study Design

The study designs used in clinical research are outlined in Fig. 89.1 and Box 89.1. In this chapter, we use the terms "retrospective" and "prospective" to describe the timing of measurement of the exposure and outcome relative to the start of the study, rather than to describe the direction of enquiry (i.e., outcome → exposure or exposure → outcome). We use the US National Institutes of Health definition of a clinical trial ("any research study that prospectively assigns human participants or groups of human participants to one or more health-related interventions to evaluate the effects on health outcomes").[16]

OBSERVATIONAL STUDIES

Observational (or nonexperimental) studies involve allowing nature or clinical care to take its course, with assignment to the intervention based on usual practice, and without any major modification due to study-related procedures, such as recruitment or data collection.[17] An observational study is not a clinical trial, therefore the contradictory term "observational trial" should be avoided. Ethical and pragmatic considerations often mean that an observational design is the only approach to answer a research question.

BOX 89.1 Study Design in Clinical Research: Depth of Anesthesia and Awareness

A ***case study*** reported on a patient who received light anesthesia and was aware.

An ***ecological study*** reported on the incidence of awareness in hospitals with low or high per-patient volatile anesthetic use.

A ***survey*** asked anesthesiologists about their routine use of light or deep anesthesia and the incidence of awareness in their practice.

A ***case-control*** study found patients with awareness, matched them with patients without awareness, and then determined if they had received light or deep anesthesia.

A ***case-cohort*** study found patients who had light anesthesia, matched them with patients who had deep anesthesia, then determined if they had been aware.

A ***retrospective cohort*** study examined existing records to determine the incidence of awareness in patients who had received light or deep anesthesia.

A ***prospective cohort*** study enrolled patients having general anesthesia and followed them to determine the incidence of awareness in patients receiving light and deep anesthesia.

A ***within-patient comparison*** of two processed EEG monitors determined each monitor's ability to predict awareness.

An ***audit*** compared current practice with a national evidence-based guideline on prevention of awareness during general anesthesia.

A ***prediction study*** reported on the development of a risk score for awareness based on a large cohort of patients having light and deep anesthesia.

A ***before-and-after*** study enrolled a cohort of patients having anesthesia without EEG monitoring and then a cohort having anesthesia with EEG monitoring and compared the incidences of awareness.

A ***randomized controlled trial*** randomized patients to light anesthesia or deep anesthesia and compared the incidence of awareness in each group.

A ***systematic review*** searched for clinical trials examining the relationship between light and deep anesthesia and awareness, and conducted ***metaanalysis*** to determine the pooled risk of awareness in patients receiving light or deep anesthesia.

EEG, Electroencephalographic.

For example, most research evaluating the impact of cigarette smoking on lung cancer relies on nonexperimental methods,[18] since assigning smoking as an intervention is unethical.[18] In general, observational studies can demonstrate associations between exposures and outcomes, but do not necessarily prove a causal relationship. Several factors must be carefully considered, including the consistency of findings across multiple high-quality studies, biological plausibility, and whether clear dose-response and temporal relationships exist between exposures and outcomes.[19] This is the case for cigarette smoking: the weight of observational research eventually established cigarette smoking as a cause of lung cancer.[18]

Since most biomedical research is observational in design, several initiatives have been undertaken to improve the conduct and reporting of such studies. For example, the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) statement makes recommendations for the reporting of three specific types of observational studies, namely cross-sectional, case-control, and cohort studies.[20] However, strong evidence that these tools improve the design and reporting of observational studies is lacking.[21]

Descriptive Studies

Descriptive studies aim to describe the characteristics of patients in a sample, such as baseline features (e.g., age, sex, comorbid disease), processes of care (e.g., anesthesia type), and outcomes (e.g., mortality, stroke). Unlike analytic studies, they do not seek to define relationships among these characteristics.

Case Reports and Series. Case reports describe exposures and outcomes in individual patients, while case series provide the same information for groups of patients. Case reports and series are suited to describing newly recognized uncommon exposures and outcomes, such as drug-related adverse effects.[22] As these studies focus on individuals with a specific exposure or outcome, no direct comparisons are possible with unexposed individuals or those without the outcome. Despite these inherent limitations, case reports and series have made important contributions to medicine. For example, a case report first identified lipid emulsion as a successful treatment for local anesthetic cardiotoxicity[23] and a case series of anesthetic-related deaths in a family first identified the pharmacogenetic disorder malignant hyperthermia.[24]

Descriptions of New Interventions. These studies are a subtype of case reports and series that describe new interventions (e.g., drugs, devices, diagnostic products, monitors, bundles of care, survey instruments, guidelines), but without any comparison against a control group. Such studies have provided valuable information to advance medicine. Important examples include the first use of the non-depolarizing muscle relaxant curare[25] and the initial clinical experience with the laryngeal mask airway.[26] With respect to diagnostic tests, "test research" determines the properties of the test itself (i.e., sensitivity, specificity, likelihood ratios, positive and negative predictive values). However, predictive values in particular are dependent on the prevalence of the outcome in the study population. A better approach ("diagnostic research") determines the extent to which adding a new diagnostic test improves the likelihood of arriving at the correct diagnosis compared with existing diagnostic criteria.[27] Diagnostic tests should always be evaluated using both methods, especially if the new test is simpler, cheaper, less invasive, or less burdensome to the patient than the existing test.[28]

Analytic Studies

Analytic studies seek to measure associations between exposures and outcomes. In contrast to descriptive studies, where all patients have the specified exposure (e.g., a laryngeal mask airway[26]) and/or outcome (e.g., successful resuscitation from local anesthetic cardiotoxicity[23]), in analytic studies patients with and without the exposure of interest (e.g., early childhood exposure to anesthesia) and outcome of interest (e.g., poor educational performance) are required in order to assess associations beyond those expected by chance alone.[29]

Ecological Studies. Ecological studies or "aggregate risk studies" measure exposure status and outcome status as average values across groups of individuals. They are particularly suited to exposures and outcomes that are routinely measured in populations. A major limitation of this approach is that exposure status and outcome status may not be linked at the individual level, leading to the "ecological fallacy," where individuals within the group-level unit with the outcome of interest may not have been the individuals with the exposure of interest. The potential for this bias was highlighted in a study of hospital-level use of neuraxial anesthesia for hip fracture surgery.[30] Higher hospital-level rates of neuraxial anesthesia use were associated with lower overall mortality, but there was no evidence of such an association at the individual level. In fact, at hospitals with higher rates of neuraxial anesthesia use, all patients had better outcomes after hip fracture surgery, regardless of the type of anesthesia they received, suggesting that the causal mechanisms for hospital-level effects were factors other than neuraxial anesthesia use.

Cross-Sectional Studies. Cross-sectional studies assess the exposure status and outcome status of individuals at the same time (or within a short and stable interval). They are suited to exposures that do not change over time, such as genetically-determined characteristics or chronic stable health conditions. Cross-sectional methods have been used to determine whether tibial nerve ultrasound can detect diabetic peripheral neuropathy[31] and whether a preoperative screening questionnaire detects obstructive sleep apnea.[32] Most surveys (see later) are cross-sectional studies since respondents typically complete the survey at a single time-point. Cross-sectional studies are ill-suited to establishing causal relationships because of the "causality dilemma" (i.e., they do not permit clear delineation of the temporal link between putative exposures and outcomes). For example, children presenting for dental treatment and their accompanying parent were tested for anxiety. Forty percent of the children and 60% of the parents were anxious preoperatively, but the investigators could not determine with any certainly if these states were related and, if so, the direction of effect.[33]

Case-Control Studies. Case-control studies assemble participants based on their outcome status; that is, patients who experienced the outcome (cases) and patients who did not (controls). Once the sample is assembled, exposure status is ascertained by looking back in time (Fig. 89.2*A*). Case-control studies are inexpensive, amenable to quick completion, and suited to the study of rare outcomes, such as postoperative stroke[34] and ischemic optic neuropathy.[35] However, they are susceptible to selection bias, especially in relation to the controls, who should be drawn from the same underlying population as the cases.[36] Thus, in a hypothetical study of stroke following cardiac surgery, it would not be appropriate to select cases who had complex aortic arch procedures and controls who had straightforward coronary artery bypass grafting procedures. Investigators can further avoid selection bias by matching cases with up to five controls based on prognostically important characteristics (e.g., age, sex), using more than one control group, and measuring exposure status with equal rigor across cases and controls (avoiding information bias).

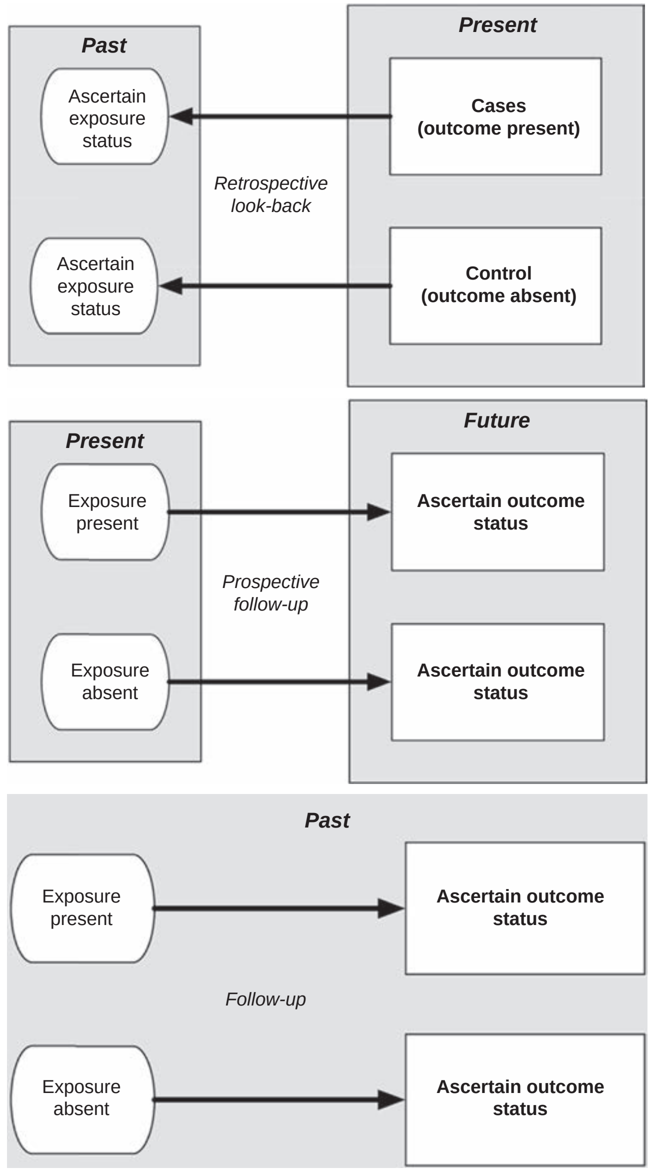

Fig. 89.2 **Observational designs.**

Cohort Studies. Cohort studies assemble participants based on their exposure status and follow them forward in time to ascertain the presence of outcomes. Both the exposure and outcome need to be relatively common to limit the size of the cohort required. Cohort studies can be conducted prospectively and retrospectively. In a prospective study, the cohort is assembled in the present and followed into the future (see Fig. 89.2*B*). This allows investigators to carefully measure exposure status (without recall bias based on knowing the outcome); delineate temporal relationships between exposures and outcomes; and implement standardized follow-up. Standardized follow-up is particularly important when the outcomes might be missed or when baseline characteristics might influence surveillance for the outcomes. For example, standardized troponin estimation is required to detect myocardial infarction and injury, because these outcomes may be silent and some patients are less likely to be tested than others (i.e., females, low-risk surgery patients).[37] Prospective cohort studies are more expensive and take longer to complete than case-control studies and retrospective cohort studies.

In retrospective cohort studies, cohort assembly and follow-up occur entirely in the past (see Fig. 89.2C). Very large databases make addressing uncommon exposures and outcomes feasible using this design. The data needed for the research (i.e., patient characteristics, processes of care and outcomes) can be captured from one or more pre-existing sources, including paper and electronic medical records, administrative and legal databases, government and clinical registries, and databases assembled for research purposes. In anesthesiology, increasing access to these sources has facilitated growth in such research.[38-40] Retrospective cohort studies are quicker and less expensive to conduct than prospective cohort studies. However, they are limited by the available data sources, which may vary in completeness and accuracy, and be influenced by the intensity of follow-up protocols. For example, the reported incidence of postoperative myocardial infarction varied considerably between prospective studies that used standardized surveillance and retrospective studies that used registries of usual clinical practice.[37,39]

Case-Cohort Studies. Case-cohort studies are a subtype of cohort studies where exposed patients are matched to unexposed patients, then followed forward in time to measure outcomes. They can be conducted either prospectively or retrospectively and are suited to the study of rare exposures. Matching reduces the influence of differences in prognostically important characteristics (e.g., age, comorbid status) between exposed and unexposed individuals. For example, a retrospective cohort study evaluating the impact of early childhood anesthesia on educational outcomes matched exposed and unexposed children based on gestational age at birth, maternal age at birth, year of birth, sex, and location of residence.[29] Matching on large numbers of baseline characteristics generally is not feasible because of the difficulties in identifying suitable individuals. In these cases, propensity score matching is an alternative that can help assemble a matched cohort with very similar baseline characteristics for both exposed and unexposed individuals.[41] Importantly, however, propensity score matching does not remove bias related to imbalances in unmeasured confounders between the groups.[41]

Studies Assessing Changes or Differences in Individuals. Some studies make serial measurements in individuals to assess changes over time. Examples include studies that characterize the pharmacokinetics and dynamics of anesthetic drugs[42,43] or postoperative acute pain trajectories.[44] These studies are a subtype of cohort study that incorporate longitudinal repeated measurement of an outcome measure. Statistical analyses of these data must account for correlated measurements in individuals over time.[45] Other studies make parallel measurements in individuals to assess differences between these measurements. Examples include comparing coagulation testing methodologies during surgery[46] or disability scoring instruments after surgery.[47] Bland-Altman analyses which test investigator-defined limits of agreement are an appropriate analysis technique when comparing tests,[48] while scales are often compared using correlation on measures such as validity, reliability, and responsiveness.[49] Some of these studies could equally be described as "experimental" (see later) because the investigators control the intervention.

Studies Assessing Practice Against a Gold Standard ("Audit"). Audits are variants of cohort studies that involve assembling a cohort of patients and determining whether practice complies with an external standard. The term "audit" is sometimes used inaccurately to describe studies that determine the standard that clinical practice achieves (i.e., evaluation) or compare practice with an investigator-derived standard (i.e., research). The extent of compliance with the standard can be compared based on different exposures. Examples of audits include the compliance of venous thromboembolism[50] and surgical site infection[51] prophylaxis with national guidelines. An important issue for such studies is ensuring that the external standard is reasonably valid and accepted within the wider community.

Studies Developing and Validating Prediction Tools. The goal of these studies is to develop tools (e.g., scores, prediction models, risk calculators) that accurately predict outcomes in individual patients. A good clinical prediction tool should be simple to use, exhibit good discrimination (i.e., the extent to which the tool correctly assigns higher predicted risk estimates to individuals who experience the outcome), and demonstrate acceptable calibration (i.e., the extent to which the observed outcome event rates agree with event rates predicted by the tool).[52] These studies first use statistical methods to evaluate associations between exposures (e.g., baseline characteristics, processes of care) and outcomes in one cohort of patients; use the results to develop scoring systems or prediction models; and then validate them in another cohort of patients.[52] Cohort study datasets are the preferred sources of development cohorts because randomized controlled trial datasets may not be generalizable.[53] Different statistical methods can be employed to develop these scores and models, including logistic regression modeling for categorical outcomes,[54] Cox proportional hazards modeling for time to event outcomes,[55] recursive partitioning (i.e., decision tree analysis),[56] and machine learning techniques (e.g., artificial neural networks).[52] Examples from the perioperative setting include the Assess Respiratory Risk in Surgical Patients in Catalonia (ARISCAT) score for predicting postoperative pulmonary complications,[57] the American College of Surgeons National Surgical Quality Improvement Program (NSQIP) calculator for predicting surgical risk,[58] and the Acute Physiology and Chronic Health Evaluation (APACHE) score for predicting hospital mortality in critically ill patients.[59]

Surveys

Surveys collect information from individuals (patients, families, staff, students) or organizations (hospitals, universities, employers) about facts and attitudes.[60] Most are cross-sectional studies assessing exposures and outcomes at the same time. Factual surveys ask for information or test knowledge. Attitudinal surveys ask about attitudes, beliefs, and intentions. Surveys can be descriptive (describing responses from the whole group) or analytic (comparing responses in sub-groups). Surveys must be carefully planned and executed in order to protect participants and provide reliable conclusions.[60,61] Response bias (non-response, incorrect response, or untruthful response) is a particular issue with survey research and must be explicitly considered in survey design and reporting.[61-63] A systematic review of 240 surveys published in six anesthesia journals revealed that reporting was inconsistent, particularly with respect to articulating a hypothesis, describing the design, calculating sample size, providing confidence intervals, and accounting for non-responders.[64] Compliance with design and reporting checklists may improve the quality of survey research.[20,61,62]

Health Services Research

Health services research (also known as health systems research or health policy and systems research) has been defined as a "multi-disciplinary field of scientific investigation that studies how social factors, financing systems, organizational structures and processes, health technologies, and personal behaviors affect access to health care, the quality and cost of health care, and ultimately our health and well-being. Its research domains are individuals, families, organizations, institutions, communities, and populations."[65] While typical clinical research focuses on the epidemiology, risk factors, prognosis, and interventions related to specific disease entities (e.g., ischemic heart disease, postoperative respiratory failure), health services research focuses on the delivery of health care. Health services research and clinical research differ with respect to their focus, but they have considerable overlap with respect to their research methodologies (i.e., how studies are designed to answer specific research questions). Thus, health services researchers also employ surveys, observational designs (as described previously), and experimental designs (as described in the section to follow). In addition, qualitative research methods are employed, such as thematic analyses of individual interviews and focus groups. Qualitative methods are particularly suited to identifying potential underlying reasons for clinician and patient behaviors within healthcare settings. Examples of health services research in the perioperative setting include a retrospective cohort study to evaluate variation in rates of preoperative medical consultation for major surgery,[66] a prospective cohort study of critical care utilization after major surgery,[67] a mixed qualitative-quantitative methods study of a standardized operating room to intensive care unit handoff process,[68] and a stepped wedge cluster randomized trial of a multifaceted implementation of perioperative safety guidelines.[69]

EXPERIMENTAL STUDIES

In experimental studies, the investigators do not let nature (or clinical care) take its course, but actively intervene to test a new intervention. Experimental studies are almost always of a parallel group design where patients or clusters of patients are allocated to an intervention or control treatment (i.e., placebo, usual care, or current best practice) by the investigators and then tested for outcomes (Table 89.1). Newer designs include cluster randomized, factorial, stepped wedge, and adaptive studies.

TABLE 89.1 Advantages and Disadvantages of Controlled Study Designs

	ALLOCATION	
Timing of Data Collection	**Randomized**	**Nonrandomized**
After intervention	Any baseline differences could bias the results.	Comparisons may be confounded by differences between departments or organizations at baseline.
Before and after intervention	Allows for specific comparison of change net of any baseline differences. Enables comparisons to be made between sites that change most or least.	Controls for baseline differences possible. Rates of change are less confounded than cross-sectional data.

Modified from Brown C, Lilford R. Evaluating service delivery interventions to enhance patient safety. *BMJ.* 2008;337:a2764.

Unrandomized Studies

If the investigator allocates the intervention or control to study patients in a nonrandom manner, this introduces selection bias and potential for imbalance between the groups at baseline in terms of risk for the primary outcome.[70] Overestimation or underestimation of the true treatment effect may then occur.

Quasi-Randomized Studies. Quasi-randomized (or quasi-experimental) studies attempt to select patients for the intervention or control in a less obvious but still nonrandom manner, for example, by surgical specialty, day of the week, date of birth, or by using a cut-off score for a certain characteristic. Quasi-randomized designs are seldom considered acceptable in contemporary clinical research because it is very hard to conceal the allocation, prevent selection bias, and ensure blinding. Some quasi-randomized designs may allow limited inference about causality (e.g., those that include a pre-test in the intervention and control groups to establish comparability). Sometimes randomization is not possible and quasi-randomized designs may be the only way to address the research question.[70] The Risk Of Bias In Non-randomized Studies of Interventions (ROBINS-I) tool helps readers to assess the quality of observational studies that evaluate interventions without the benefit of randomization.[71]

The before-and-after study is a simple and tempting study design that has been used for centuries to compare patient status before and after a new intervention. For example, John Snow compared the incidences of cholera in a neighborhood of London before and after removing the local water pump handle.[72] In modern research, these studies can be conducted entirely prospectively, partly prospectively (the "after" group), partly retrospectively (the "before" group), or wholly retrospectively.[73] The "before" intervention is often current usual care and the "after" intervention is often a new treatment. For example, an enhanced recovery pathway for colectomy patients was reported to be associated with decreased opioid administration, earlier return of bowel function, and reduced length of hospital stay compared to the old approach.[74] The methodological challenge here is the influence of time: these improvements could have resulted from the new pathway or from changes in case-mix or unmeasured parallel improvements in care. If the effects of such parallel improvements are large enough, they might even obscure the fact that the new pathway is actually worse in terms of patient outcomes. Difference-in-differences approaches can be used to address time-related trends in outcomes. These approaches assume that trends unrelated to the exposure are the same in both groups.[75] Before-and-after studies are particularly vulnerable to the Hawthorne effect (i.e., the observation that people perform better when they know that they are being observed). The observational study design in which data are collected in individual patients before and after an intervention is addressed above.

Cross-Over Studies. The cross-over study is a more robust form of the before-and-after design. Here each patient receives all the interventions and control treatments, separated by wash-out periods to eliminate carry-over effects from the previous treatment.[76] Cross-over studies are well suited to patients taking chronic medications (e.g., analgesics for chronic pain[77]). A major benefit of the cross-over design is that patients are their own controls, which eliminates the confounding issues seen in parallel group designs. The order in which patients receive the intervention and control treatments can be nonrandom or random (the latter will eliminate time effects). In addition, administration of the intervention and control treatments can be blinded to eliminate placebo and nocebo effects.[78]

Randomized Studies

The ascendency of large simple randomized trials as the most robust form of primary research in anesthesia, intensive care, and pain medicine had its roots in the evidence-based medicine movement.[79] The cardinal features of a high-quality randomized controlled trial are successful randomization and blinding, and a sufficient sample size to reveal clinically important treatment effects on patient-centered outcomes.

Randomization. The many methodological problems associated with observational studies and nonrandomized experimental studies boil down to the distorting influence of confounders (see above).[80] The purpose of random allocation is to ensure that all confounders (known and unknown) are evenly distributed between the intervention and control groups at baseline. The success of randomization in evenly distributing these characteristics is critically dependent on the sample size of the study. After successful randomization any remaining differences in baseline characteristics will be the result of chance alone and patients in the intervention and control groups should have the same probability of experiencing the primary outcome. The study will then have a small likelihood of distorted results from random and systematic error. This is the primary reason that large randomized trials are considered the gold standard for experimental studies in medicine.[79] Randomization schedules can be generated using simple, block, stratified, or covariate adjusted techniques.[81] Allocation concealment is an essential step in preventing selection bias (i.e., recruiting patients based on knowledge of the treatment to which the next study patient will be allocated).[82]

BOX 89.2 Phases of Clinical Trials

Phase I

Phase I trials test a new intervention for the first time in a small group of participants to evaluate safety.

Phase II

Phase II clinical trials study a new intervention in a larger group of participants to determine efficacy and further evaluate safety.

Phase III

Phase III trials study the efficacy of a new intervention in a large group of people by comparing it to other interventions or routine care and monitor adverse effects.

Phase IV

Phase IV trials study an intervention after it has been marketed, and monitor its effectiveness in the general population, collect information about adverse effects, and investigate its use in a different condition or in combination with other therapies.

Blinding. Randomization can effectively eliminate confounding, but it is not enough to guarantee unbiased results. Simply knowing about the treatment allocation can influence the behavior of the investigators, subsequent clinical management by the treating team, and even the symptoms that the patients experience, creating a new imbalance in confounders and undoing the benefits of randomization. The solution here is blinding: hiding the treatment allocation from the observers collecting study data, the patient, and/or the treating team.[83] Blinding observers, patients, and treating team members in phase III and IV drug trials (Box 89.2) is the norm, as matched blinded experimental and control drugs are easy (although not inexpensive) to produce.[84] Other interventions are harder to blind (e.g., intravenous albumin solutions[85]) and others cannot be blinded (e.g., epidural local anesthetics in chronic pain patients[86]). In such cases, it is important to conceal allocation as long as possible to prevent this knowledge from influencing processes of care. Every effort should be made to blind outcome observers in randomized trials.

Superiority, Equivalence, and Non-Inferiority. Randomized trials are often geared toward demonstrating that the intervention results in better outcomes than the control (“superiority”).[87] However, a randomized trial can be designed to demonstrate that the two treatments produce the same results (“equivalent”)[88] or that the one produces results at least as good as the other (“non-inferiority”).[89] Equivalence and noninferiority designs are useful if the new intervention might be simpler, safer, and/or cheaper than the current treatment, and demonstrating equivalence or non-inferiority would be sufficient to change practice.

Factorial Designs. Factorial designs allow testing of more than one intervention in a single clinical trial.[90] Rather than performing a separate randomized trial for each intervention and each combination, patients in factorial studies are separately randomized to two or more different interventions (that is, they receive none, some, or all of the experimental interventions). This design is efficient and allows testing of interactions between the interventions.

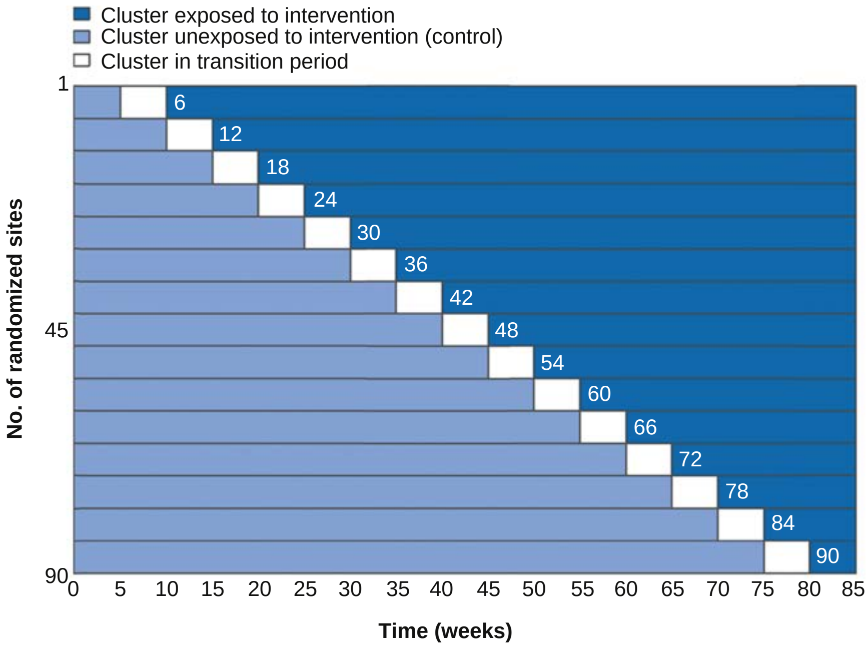

Fig. 89.3 Stepped wedge design.

For example, in a factorial trial of six interventions for the prevention of postoperative nausea and vomiting, 4000 patients were randomized to one of 64 possible combinations of six antiemetics.[91] This design allowed the investigators to conclude that these antiemetics were similarly effective and acted independently. In another example, 5784 patients were randomized to aspirin or placebo, and in a partial factorial, 4662 of these patients were also randomized to tranexamic acid or placebo.[92,93] This allowed the investigators to determine that there were no interactions between the interventions with respect to death, thrombotic complications, or major hemorrhage.

Cluster Randomized Designs. Most studies are randomized at the patient level. Cluster randomized trial designs are needed when randomization at the patient level is not possible or is methodologically unsound. This is particularly the case for process of care interventions because the fidelity of the intervention is dependent on the execution by the treating team and blinding is often not possible.[94] Examples include cross-over cluster randomized trials of selective decontamination of the gut in intensive care patients (even though the intervention is only applied in patients randomized to the treatment group, changes to bacterial colonization profiles will extend to all the patients in the unit)[95] and randomized trials of the introduction of medical emergency teams to treat deteriorating hospital patients.[96]

Stepped Wedge Designs. Cluster randomization means that some hospitals or clinical areas implement the new intervention, and some must remain with the existing model of care. Before-and-after studies are contaminated by the effects of time and cross-over cluster randomized trials have the disadvantage that clusters that were first randomized to the new intervention must revert to the existing model of care. A stepped wedge design circumvents some of these ethical and methodological issues by ensuring that each cluster first provides data for the control condition and then crosses over to the new intervention (Fig. 89.3).[97,98] This may improve recruitment of centers and patients. The duration of these periods differs for every cluster, but at the end of the study period there will be an equal amount of data from control and intervention periods. This eliminates—to a large extent—the effects of time. Stepped wedge designs were originally used in vaccination studies, exploiting the natural limitation that vaccination programs can never be rolled out over an entire region in a very short time frame.[99] They are considered alternatives for randomized trials of complex interventions, provided that there is a high likelihood of a positive effect of the intervention and a very low risk of harm.[97]

ANALYSES OF PUBLISHED RESEARCH

Systematic Reviews

The explosion in published medical knowledge and the requirement for quick answers to urgent clinical questions means that reliable synthesis of the medical literature is invaluable. Traditional narrative reviews are prone to author biases (sometimes even outright conflicts of interest), because authors can “cherry pick” the literature for evidence supporting their own opinions. Systematic reviews pose an explicit research question and publish a transparent search strategy that every reader can replicate and update.[100] The Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) statement is available to guide authors of systematic reviews.[101] However, the quality of reporting and methodological quality of reviews remains inconsistent.[102]

Metaanalyses

When multiple randomized trials have addressed similar research questions, interventions, and outcomes, the results can be mathematically aggregated in a metaanalysis,[100] the goal of which is to estimate the aggregated effect of the intervention. A high-quality metaanalysis of large

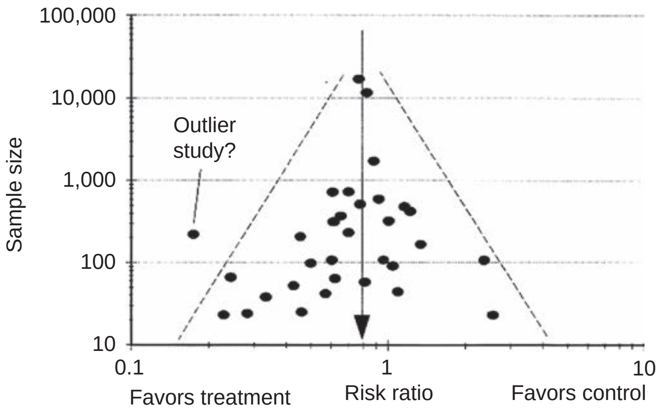

Fig. 89.4 Funnel plot showing publication bias: overrepresentation of studies with small sample sizes showing larger treatment effects.

well-conducted randomized trials is considered the highest level of evidence to guide practice, although results of meta-analyses do not always agree with subsequent very large trials.[103] The Cochrane Collaboration is dedicated to performing systematic reviews and metaanalyses that inform clinical practice. The Collaboration's software tools ("RevMan" and "Covidence") generate analyses, graphs, and metrics about the quality of included studies.[104,105] Funnel plots of treatment effect against study precision are used to detect publication bias toward studies with large treatment effects (typical of small trials) (Fig. 89.4).

Individual Patient Metaanalysis

A more powerful form of metaanalysis aggregates results using individual patient data, rather than aggregated data from the included studies.[106,107] The benefits of this approach are better characterization of outcomes and the opportunity to perform new subgroup analyses. The challenges of this approach include obtaining the raw data (with one paper reporting that only 25% of these meta-analyses retrieved all individual patient data[108]) and reliably merging trial databases containing the original data into the new pooled database. A standard aggregated data metaanalysis will illuminate whether an individual patient data metaanalysis will yield sufficient new information to justify the additional time and effort.

Study Protocol

A carefully designed protocol is the foundation of all clinical research, facilitating the review, conduct, and eventual publication of the study (Fig. 89.5).[109] However protocols are often incomplete and inconsistent with their corresponding published reports.[110,111] In response, templates have been developed, including by the World Health Organisation,[112] the International Council for Harmonisation,[113] national research funding agencies,[114] and the Equator Network (the Standard Protocol Items: Recommendations for Interventional Trials [SPIRIT] statement[115,116]). The effectiveness of these templates in improving the quality of protocols is yet to be determined. Amendments to clinical research protocols must be approved by the coordinating institutional review board (human research ethics committee) and must be reflected in the trial's registration. The International Committee of Medical Journal Editors recommends that investigators make their protocols publicly available before any results are published, for example by posting them on institutional websites or publishing them in peer-reviewed journals.[117]

HYPOTHESES

All clinical research—from a case report through qualitative and observational projects to a multicenter clinical trial—begins with a research question. These questions arise from a myriad of sources: the existing literature, the previous work of the investigators, interactions with colleagues, observations during clinical work, and discussions with patients and their families. A well formulated research question guides the literature review (which establishes the need for the study); informs the study design, methods, and sample size; and limits the potential for error and bias.[118] The Population-Intervention-Comparator-Outcome-Time-frame-Setting (PICOTS) format is a popular framework among clinical researchers[119] and improves the quality of research questions.[118] In an observational study, the "intervention" and "comparator" can be patient-based (e.g., with or without intraoperative hypotension) or care-based (e.g., treated in a metropolitan or rural hospital). In a clinical trial, the intervention and comparator are randomized. During protocol development, research questions are transformed into formal hypotheses. The structure of the hypothesis depends on whether the investigators predict that one group will have superior, equivalent, or non-inferior outcomes to the others. Regardless of this prediction, two-sided hypothesis testing is preferable: that is, entertaining the possibility that standard treatment is better or that the treatments are not equivalent.[120]

POPULATION

Selection of participants depends on the purpose and context of the study, and is a key differentiator between explanatory and pragmatic studies.[121,122] Explanatory (efficacy) studies, such as observational studies of new drugs and devices or phase I to III clinical trials, include highly selected patients in highly controlled settings, to reduce variability between patients and maximize treatment effects. The generalizability of explanatory studies therefore is limited. Pragmatic (effectiveness) studies, such as phase IV clinical trials, include typical patients receiving real-world care.[123] Random sampling is approximated by approaching all patients who have indications for the treatment and who present themselves for care. In practice, however, only a subset of patients is approached. Further nonrandom selection occurs when patients decline to participate or fail to complete data collection.[122] Although national funders promote diversity among participants,[124] children, elderly people, pregnant and lactating women (indeed, women in general), culturally and linguistically diverse people, and people with disabilities are still underrepresented in clinical research.[125-127] An additional factor is failure to identify underrepresented people (e.g., transgender people) among recruited participants.[128] Ideally studies should be powered to allow analysis of major sub-group effects.[124,126]

INTERVENTIONS AND COMPARATORS

Nearly all clinical research involves an intervention (e.g., a drug, device, procedure, diagnostic test, bundle of care, etc.). In observational studies, the intervention is administered as part of usual care, whereas in experimental studies the intervention is administered by or on behalf of the investigators. Many studies involving an intervention also involve a comparator (e.g., placebo, usual care, or current best practice).[129] The comparator should be the best proven intervention, except when no such intervention exists.[109] In this case, a placebo may be appropriate. Usual care needs to be defined at the outset and monitored for change over time. Current best practice needs to be supported by guidelines and ensured during the study.[129] For a study to be ethical, there must be uncertainty in the expert community about the relative merits of the intervention(s) and comparator(s), and the study must be designed to resolve it (clinical equipoise).[130] Complex perioperative interventions and comparators may not be fully or properly implemented in pragmatic studies, and this variation may be nonrandom. For this reason, patients are usually analyzed in the groups to which they are assigned (intention-to-treat analysis).

OUTCOMES

Outcomes are events that may result from or be associated with an action taken during a study. Ideally, outcomes in clinical research influence the way clinicians practice and the choices that patients make.[131] Although patient-reported outcomes are subjective, they can greatly enhance the impact of the study if properly developed and implemented.[132,133] Binary outcomes that can be expressed as probabilities are easier to interpret than continuous outcomes, which can be converted to binary outcomes by defining an appropriately validated cut-off value.[131] Composite outcomes can be a useful means of assessing the impact of an event or intervention but can be misleading if the components are dissimilar in frequency, magnitude, direction of effect, or importance.[134] Surrogate outcomes occur between the event or intervention and the true outcome, and are used to draw conclusions about the true outcome. To be valid, the relationship between the surrogate and true outcome must be precisely defined.[135] Occasionally surrogate outcomes indicate the direction and magnitude of the effect of the intervention on the true outcome (e.g., the effect of anti-arrhythmic drugs on ventricular ectopic beats and sudden death post-myocardial infarction[136]). The primary outcome is the focus of the study and will be the basis of the sample size calculation. Secondary and safety outcomes should reflect the important beneficial and adverse effects of the event or intervention. Careful definition of outcomes and the timing of their measurement are fundamental to protocol development.

SAMPLE SIZE

A study needs a sufficient number of participants to provide reliable conclusions about the specified outcomes and treatment effects. If the number of study participants is too low, the investigators could incorrectly conclude that there is no treatment effect.[137] If the number of study participants is too large, it may delay the availability of information that is vital to patient care. In both cases resources will be wasted and participants will be exposed to unnecessary risk. A sample size calculation therefore should be conducted in the design phase of all studies. In qualitative and observational research, investigators should justify the reasons for their sampling frame (the population from which the sample is drawn).[20] This should be based on the availability of interviewees or relevant data in an appropriate format, or the investigators' expectations about the numbers of eligible participants and/or their estimates of acceptable 95% confidence intervals around the incidence of the primary outcome.[138] In comparative studies, sample size calculations are based on the expected difference in the primary outcome between the groups (effect size), the variance in the effect size (for continuous variables), and the risk that the investigators are willing to accept of false positive (α; type 1 error) and false negative (β; type 2 error) findings.[139,140] Effect sizes and variances can be estimated from the literature, pilot studies, statistical methods, or opinions about minimal clinically important differences.[141] The planned sample size will also depend on the number of groups, number of anticipated dropouts, and statistical analyses planned. The protocol should provide sufficient information to allow replication of quantitative sample size calculations.[138,140] In the anesthesia literature this is frequently not the case.[142] Post hoc calculation of statistical power using the results of a trial is inappropriate; the width of the confidence intervals around the primary outcome is a better indicator of the reliability of the result.[140]

DATA ANALYSIS PLAN

The details of data analysis are outside the scope of this chapter, and increasingly outside the scope of clinician researchers and reviewers.[143] Statistics training or collaboration with biostatisticians or experts in qualitative data analysis is commonly required to reach the level of statistical excellence required by regulators, funders, and journals. Statistical input is vital during the planning of clinical research, particularly in relation to the sample size calculation. The protocol should also include a plan for description of the data and analyses of the primary and secondary outcomes, subgroup and adjusted analyses, sensitivity analyses, interim analyses and stopping rules, and protocol adherence, as applicable.[115,116,144-146] The detailed statistical analysis plan for large observational studies and clinical trials is often published before the unblinded data are available, and at least should be predefined.[147] Peer-reviewed journals may require submission of the statistical analysis plan with the manuscript, require statistical checklists, and employ statistical editorial teams to assist with the evaluation of manuscripts.[143,146]

SUPPORTING STUDIES

Feasibility and Pilot Studies

Most clinical studies are inspired by prior research of some kind. Increasingly, however, preliminary work is specifically undertaken to demonstrate the viability of a future large observational or experimental study.[148,149] A feasibility study tests whether a future study can be done,[150] examining the knowledge and interest of practitioners, availability of eligible patients, their willingness to participate, ease of applying the intervention and collecting data, qualities of the primary outcome, and resource requirements of the study. A pilot study is a type of feasibility study that tests the proposed hypotheses of a future study, without being scaled to test the effectiveness of interventions nor the strength of associations.[130] Pilot studies are frequently used to inform sample size calculations for the future studies, although this process may be flawed.[151] The rationale for the sample size of the feasibility study itself should be congruent with the feasibility objectives, but need not involve a formal sample size calculation.[150] Pilot studies are subject to the same ethical and regulatory requirements as definitive studies.

Sub-Studies

Sub-studies are an efficient means of investigating additional research questions using additional data collected in subsets of participants in large clinical trials. They are subject to the same ethical and regulatory requirements as the main study, and ideally are planned simultaneously. Substudies can investigate additional outcomes related to the randomized intervention, in which case they can be considered nested randomized trials.[152,153] They can investigate the associations of additional unrandomized exposures (e.g., biomarkers) with the same outcomes, in which case they can be considered nested cohort studies.[152,154] Finally, they can investigate the associations of additional unrandomized exposures with additional outcomes: these are also nested cohort studies and are an efficient use of a unique cohort.[152,155] The effect of additional randomized exposures is more properly evaluated using a factorial study design. Principal design considerations for sub-studies include adequate sample size and limiting the burden on investigators and patients.

Sub-Analyses

Sub-analyses are an efficient means of investigating additional research questions using data collected for another primary research purpose. Some sub-analyses are planned before the main study begins (e.g., population subgroup analyses). Others are planned after the data have been collected or the main results have been published and may address unanticipated events or discoveries. In any case the statistical analysis plan should be finalized before the analyses begin.[147] Sub-analyses can investigate the associations of unrandomized exposures (e.g., baseline characteristics, processes of care, measured variables) with the primary and secondary outcomes,[156,157] or the detailed effects of the randomized intervention on secondary outcomes.[158,159] Propensity scoring methods are increasingly used to determine the probability of a participant receiving a nonrandomized treatment given a particular set of baseline characteristics, and to compensate for this by stratifying, matching, weighting, or adjusting on the basis of the propensity score.[156,160,161] However these methods are heavily reliant on the collection of appropriate and complete baseline data, and do not reduce confounding by unmeasured or unknown factors (e.g., the reasons the anesthesiologist chose a particular technique or defended a particular blood pressure).[160,161]

Ethical and Regulatory Considerations

ETHICS APPROVAL

All research on humans must be conducted within a system that ensures the safety and privacy of the participants.[109,113,162-166] This system can be local, national, or multinational. The degree of scrutiny is based on the potential for risk, discomfort, inconvenience, burden, and threats to privacy. Depending upon the jurisdiction, low-risk research (e.g., audits and surveys) may be conducted without review under policies that promote ethical conduct, or under expedited review processes.[164,166] Research that is not low-risk is considered by an institutional review board. The board approves the processes for obtaining consent or may waive or qualify consent if the risk to participants is low.[109,113,162-165] Deferred consent is also possible in urgent care research in some jurisdictions.[166] Approaching patients for the first time about a study on the day of surgery is acceptable to patients,[167,168] but participation rates are lower than before the day of surgery.[169]

REGISTRATION

Clinical trial registration was introduced in response to concerns about publication bias and selective reporting.[170] Additional aims of registration include reducing waste from unnecessary duplication of studies and improving access to clinical trial participation and results for patients.[171] Initial efforts involved mandating registration of a minimum dataset of protocol information before the enrollment of the first patient.[117,172] Subsequently efforts were expanded to mandating public disclosure of aggregated trial results, including those that were negative or inconclusive.[16,109,172-174] These efforts have not been completely successful.[171] For example, in a report about anesthesiology registration, although rates of registration had improved since 2007, 62% of clinical trials published in six specialty journals in 2015 were still inadequately registered.[175] Further culture change among funders, institutional review boards, investigators, and publishers will be required.[171,176] Registration of observational research is encouraged,[177] but is currently voluntary, partly because of concerns that registration may stifle exploratory analyses.[178]

REGULATORY APPROVAL

Federal, national, and state government agencies regulate the manufacture, import/export, supply, marketing, and surveillance of drugs and medical devices, with the aim of optimizing access to safe and effective therapeutic goods. There is some harmonization between jurisdictions.[179,180] Regulatory authorization is required for clinical trials of therapeutic goods that are not yet approved (phase I-III trials) or are being tested for an indication outside the current approval (phase IV trials).[181] The sponsor, institutional review board, and regulator collaborate in protecting patients who are exposed to unapproved therapeutic goods during clinical trials. This collaboration can be especially complex for international investigator-initiated clinical trials, and must be carefully considered in the planning phase.

DATA SHARING

Sharing of individual patient data from clinical trials is in the public interest, on scientific, economic, and ethical grounds.[182] Third parties may wish to verify trial results, correct errors, explore new hypotheses, or use the data in individual patient data metaanalyses.[175] Funding agencies, publishers, investigators, and the pharmaceutical industry have issued position statements about data sharing.[182-185] Retreating from its initial proposal of mandating data sharing,[186] the International Committee of Medical Journal Editors currently requires investigators to include a data sharing plan in the trial's registration and a data sharing statement in the primary manuscript.[184] These statements and plans must disclose whether, what, with whom, and how data will be shared. This position recognizes the current lack of policies, resources, and culture that will protect the interests of patients and investigators.[184] In order to be effective and responsible, data sharing must be planned from the outset of a clinical trial, as it involves clarifying the need for patient consent, constructing appropriate data management systems, and securing adequate funding.[185,187]

Study Management

FINANCIAL MANAGEMENT

Good clinical practice requires investigators and sponsors to document and agree on the financial aspects of a study.[113] Budgets and contracts are approved as part of the research governance process. All clinical research has a cost: even a case report requires retrieval of medical records, preparation of illustrations, and investment of investigator time. The cost of research is increasing in line with the increased size and complexity of clinical research. At the same time, the ability or inclination of health services to absorb costs that are not directly related to patient care is decreasing. Investigators therefore must obtain funding from other sources, including government agencies, commercial enterprises, and philanthropic organizations. This process can be time-consuming and stressful.[188] One study estimated that 34 working days of the principal writer's time was spent preparing each new proposal for a national funding round.[189] Only 20% of these proposals were funded. Streamlined and flexible application processes, and rules regarding resubmission of unsuccessful proposals, may reduce workload and increase success.[188,189]

DATA MANAGEMENT

The protocol should list each item of data to be collected, its source, and the timing of measurement.[115] The ethics review process addresses whether the proposed data collection meets privacy and data security requirements.[113] In explanatory studies, such as phase I-III clinical trials, the volume of data collected can be large, whereas in pragmatic studies data collection should be limited to vital measurements only.[190] Three main options are available for data collection: (1) a bespoke case report form; (2) data extraction from existing sources (such as medical records, registries, and administrative databases); and (3) a hybrid approach.[190] Case report forms can be printed or electronic, with electronic forms offering mechanisms to ensure complete and accurate data entry.[191] Data will then be transferred to a database that is usually established specifically for the study. Increasingly anesthesia research protocols require linkage of records of individual patients or groups across unrelated databases, requiring the input of health informaticians and raising issues of privacy and data security.[192]

HUMAN RESOURCE MANAGEMENT

The human resources associated with clinical research include the investigators, trial coordinators, treating clinicians, and patients. Ethics and governance processes address whether the legitimate interests and rights of these parties are protected during the study.[113] Investigators and trial coordinators should be suitability qualified, experienced, and competent for the research they propose to undertake, and ideally should have International Council for Harmonisation E6 Good Clinical Practice certification[113] (a requirement of some funding bodies[193]). Clinical trial networks can play a big role in nurturing careers and fostering collaboration. Treating clinicians need to be advised about their role in implementing the protocol and be engaged in ensuring the success of the study. This is especially important in protocols that require the continuous attention of the treating clinician during an anesthetic[194] or critical care unit stay.[85] Recruiting patients to anesthesia and critical care studies can be difficult, because of time constraints and multiple competing priorities. A systematic review of recruitment strategies identified that open rather than blinded treatment allocation, and phone follow-up to written invitations to participate, significantly improved recruitment.[195] Loss to follow-up is very low in anesthesia and critical care studies, because time frames for data collection are often short and patients are in the operating room or hospital for most or all of the study.[85,156,194] A systematic review of retention strategies in ambulatory settings reported that only monetary incentives improved retention.[196]

ADVERSE EVENT REPORTING

Adverse event reporting is a crucial step in ensuring the safety of participants in all clinical research (Box 89.3).[197] An adverse event is any unfavorable and unintended occurrence associated with the use of a medicinal product, whether or not it is related to that product. Adverse events can be categorized by severity (intensity), seriousness (effect on patient outcome), expectedness (observed before), and causality (attributability to the medicinal product).[197] Expedited reporting of adverse events to regulators and institutional review boards is an essential part of phase I to III trials.[172,198] For phase IV trials, universal safety endpoints and unexpected adverse events are reported periodically by the trial's data and safety monitoring board. Only serious unexpected events that would be reported as part of routine clinical care are reported immediately to regulators and institutional review boards. The primary report of a clinical trial should include a table of adverse events by system and/or severity.[172,198] Adverse event reporting is burdensome and costly, and therefore should be aligned with the risk to patient safety of the medicinal product.[199-201]

BOX 89.3 **Definitions of Adverse Events in Clinical Research**

Adverse event: Any untoward medical occurrence associated with the use of a drug in humans, whether or not considered drug related.

Suspected adverse reaction: Any adverse event for which there is a reasonable possibility that the drug caused the adverse event.

Unexpected: Any adverse event or suspected adverse reaction that is not listed in the investigator brochure (or general investigational plan) or is not listed at the specificity or severity that has been observed.

Serious adverse event or suspected adverse reaction: Any adverse event or suspected adverse reaction that results in any of the following outcomes: death, a life-threatening adverse event, inpatient hospitalization or prolongation of existing hospitalization, a persistent or significant incapacity or substantial disruption of the ability to conduct normal life functions, or a congenital anomaly/birth defect.

Life-threatening: An adverse event or suspected adverse reaction that places the patient or subject at immediate risk of death. It does not include an adverse event or suspected adverse reaction that, had it occurred in a more severe form, might have caused death.

MONITORING AND AUDIT

Monitoring is "the act of overseeing the progress of a clinical trial."[113] All clinical studies require some monitoring, to ensure that participants are protected; the study is being conducted in accordance with its approvals; and the data are complete, accurate, and verifiable.[113] Monitoring may range from simple checks by the investigators through on-site monitoring by the sponsor or a contract research organization. Increasingly, centralized monitoring is being used to look for data trends and integrity issues.[202] Audit is "a systematic and independent examination of trial related activities and documents."[113] Audits are conducted by institutional review boards, regulators, and funders, sometimes after a concern is raised about a study. In clinical trials, quality management is the responsibility of the data and safety monitoring board. The board can review unblinded data and adverse event reports, and make assessments about the evolving balance between efficacy and risk in the study. Boards and board members need to be independent, and increasingly need to be trained for the heavy academic, legal, and ethical responsibilities involved.[203]

Study Reporting

MANUSCRIPT

Accurate, complete, and timely reporting of results supports research integrity and usefulness. Reporting guidelines are available for a wide range of study designs and populations, and compliance with these guidelines and completion of checklists and flow diagrams is mandated by some journals.[117,204] For example, the STROBE and Consolidated Standards Of Reporting Trials (CONSORT) statements aim to improve the quality of reporting of observational studies and randomized trials respectively.[20,138-140] The quality of reporting of randomized controlled trials has improved over time, but it is unclear if this is due to the CONSORT statement.[205] A systematic review about the effect of journal endorsement of the statement on quality of reporting identified a significant improvement in reporting for only five of the 27 items,[206] highlighting the need for research into adherence to guidelines.[207] Research is only useful if the investigators communicate effectively with their intended audience. As well as reporting guidelines[204] and instructions from journal editors,[117] researchers are advised to consult resources about writing clear and graceful prose.

AUTHORSHIP

Investigators can be involved in the concept, design, funding, governance, management, data collection, analysis, and/or reporting of clinical research. The International Committee of Medical Journal Editors recommends that authorship be based on substantial contributions to the research, approval of the submitted manuscripts, and agreement to be accountable for all aspects of the work.[117] Honorary authorship to recognize contributions that do not meet the recommendations (such as leading the department in which the work was done or technical editing of the manuscript) is thereby prohibited. Criteria for authorship and for acknowledging non-author contributions should be established before the research commences and reviewed at manuscript submission.[117,208] With increases in numbers of authors, multi-investigator groups, and data sharing, solutions to acknowledging contributions to research are rapidly evolving.[208-210]

PUBLISHING

Researchers need to choose their target journal with care, taking into consideration the subject and potential impact of their research, the requirements of funders for open access publication, and the bona fides of the target journal. Legitimate publishers conform to recognized standards of publication ethics.[117,211] Open access options are available for a fee in traditional subscription journals and legitimate open access journals. So-called "predatory" open access journals aggressively seek submissions through "spam" email, do not conform to ethical standards, and may charge high fees without delivering on open access or indeed publishing at all.[212,213] Various resources are available to help authors identify predatory journals, although these are imperfect due to increasing numbers of both legitimate and predatory journals.[212-214]

RESEARCH INTEGRITY

Research integrity is "active adherence to the ethical principles and professional standards essential for the responsible practice of research."[215] Research misconduct includes fabrication, falsification, plagiarism, misleading reporting, redundant publication, abuse of authorship, conflict of interest infringements, funding infringements, fraud in the peer review process, and unethical research (in particular, in relation to patient consent and protection).[216-218] Research misconduct damages the reputation of science and scientists, and is a threat to patient safety. A systematic review on interventions to improve research integrity concluded that the evidence for effectiveness was sparse, of low quality, and concentrated on short-term outcomes.[219] Plagiarism, which ranges from intellectual theft through careless practice to self-plagiarism (not strictly speaking plagiarism but possibly duplicate publication),[220] is the most common form of research misconduct.[221] Practical training may reduce plagiarism[219] and routine screening using text-matching software may reduce plagiarism in submitted papers.

Reflection, Feedback, and Forward Planning

Continuous quality improvement is now mainstream in clinical practice and medical education.[222] Practitioners and students are encouraged to reflect on their experiences; note what they did well and where they could do better; discuss these reflections with their supervisors or teachers; and give their colleagues or teachers feedback about the quality of the workplace or learning environment. At the end of this cycle plans are made for the future. Researchers could benefit from a similar cycle of reflection, feedback, and forward planning. While a lot of helpful information and training about designing and conducting clinical research is available, including in *Miller's Anesthesia*, each researcher has unique aptitudes and works in a unique context. We recommend that researchers keep a journal about each research project, reflect on their experience when the project is completed, and share strategies for success with their peers and junior colleagues. Finally, as well as giving patients an opportunity to contribute to study design, giving patients an opportunity to comment on the results of studies in which they participated might give researchers fresh insights and open up new avenues of research.

90 Interpreting the Medical Literature

ELIZABETH L. WHITLOCK and CATHERINE L. CHEN

KEY POINTS

- The medical literature can be accessed in many ways, ranging from the primary literature as indexed in sources like PubMed, to sources catering to medical professionals, and via the lay press and social media as well.
- The quality of medical literature varies widely, as does the interpretation or distillation into secondary sources of information.
- The traditional "evidence pyramid" no longer effectively reflects the diversity and impact on clinical care of the rapidly evolving body of medical knowledge.
- Understanding the design of a research study is crucial to understanding the strength and implications of its conclusions.
- Different research study designs have assessment tools, maintained by the EQUATOR Network, to assist in understanding the quality of the study.
- Statistical analysis is commonplace in original research manuscripts, but the interpretation of statistical results, particularly the probability or "*P*-value," is widely misunderstood and misused.
- Although the hallmark of the primary medical literature is a rigorous peer review process, there are serious pitfalls that may be difficult to detect, including predatory journals and reviewer misconduct.

Introduction

Reading and interpreting the medical literature is a critical skill for any practicing anesthesiologist. The numerous scientific advances made over the last few decades make it imperative for anesthesiologists to understand how to read, interpret, and apply the medical literature to the clinical scenarios that arise in daily practice. **Critical appraisal,** a concept that first arose in the early 1980s,[1] is "the process of carefully and systematically examining research to judge its trustworthiness, and its value and relevance in a particular context."[2] The idea that clinicians "should practice medicine in a way that combines research evidence with clinical skills and patient values and preferences" led to the creation of a new approach to caring for patients called "evidence-based medicine," a term first coined in the early 1990s by Gordon Guyatt at McMaster University.[3]

In response to this new approach to patient care, where the most recent published evidence could be used to support clinical decisions in lieu of the usual approach of deferring to a physician's seniority, intuition, or prior experiences with similar patients, the *Journal of the American Medical Association* published a series of articles entitled "Users' Guides to the Medical Literature" in the early 1990s that has since been formatted into a textbook by the same name.[4,5] This text is an excellent resource for those who are interested in effectively incorporating the systematic evaluation of the medical evidence into their daily clinical practice. We do not purport to write as complete a chapter on interpreting the medical literature as the existing resources that are already available to the lay reader.

This chapter is, however, intended to provide some basic information about how medical evidence is created and published, some useful tools for evaluating the medical literature, and to highlight some of the pitfalls to avoid when sorting through the litany of information available to both physicians and to the lay public. The previous chapter provided an introduction to the different study designs used in clinical research and their relative strengths and weaknesses. This chapter will aim to put the key points raised in the previous chapter within the context of how research can be interpreted and used by a clinical anesthesiologist.

INTENT OF THE CHAPTER

The goals of this chapter are: (1) To provide a brief overview of how a research manuscript is treated from the moment of submission to its publication date; (2) to provide a practical guide for accessing, interpreting the quality of, and implementing the knowledge gained from reading the medical literature; and (3) to identify and avoid the pitfalls of indiscriminate use or the misuse of the published evidence.

The Publication Process

TYPES OF JOURNALS

With the advent of the Internet, researchers and consumers of research have an overwhelming array of journals to consider for submitting and reading original work. A journal's focus and target audience can vary. Some journals are known as **general medical journals** because they include work from many different fields within medicine. Examples include *The New England Journal of Medicine (NEJM)*,[6] *Journal of the American Medical Association (JAMA)*,[7] *The BMJ (formerly known as the British Medical Journal)*,[8] and *The Lancet*.[9] Most medical journals, however, focus on a particular medical specialty, or they may highlight particular topics such as research methods or health policy.

Journals can be accessed as printed and bound periodicals requiring an active print subscription, through a designated website offering a selection of free articles or articles requiring payment to view, or often by using a combination of the two delivery methods. The quality and reputation of journals can vary greatly—some require little to no peer review and an upfront payment in exchange for quick online publication of a manuscript of questionable quality (see *Predatory Journals*, later). Others maintain extremely high standards for manuscript acceptance and editorial review. Publication in a medical journal with an established history as a traditional print journal, even while it maintains a distinct web presence, is usually an indicator that a published manuscript has been subjected to peer review and represents a worthwhile contribution to the medical literature.

A number of professional societies in anesthesiology publish journals of peer-reviewed literature relevant to the field and include some of the most reputable journals within the field, such as the American Society of Anesthesiologists *(Anesthesiology)*,[10] the Royal College of Anaesthetists/The College of Anaesthetists of Ireland/the Hong Kong College of Anaesthesiologists *(British Journal of Anaesthesia)*,[11] and the International Anesthesia Research Society *(Anesthesia & Analgesia)*.[12]

TYPES OF JOURNAL ARTICLES

Although each journal's priorities for content may vary, for the most part, journals publish similar types of articles. These article types can be grouped into the following broad categories: original research, review articles, brief reports or letters, case reports, and editorials.

Original research is the most familiar and most common type of article that gets published. Original research usually consists of a scientific manuscript that reports the full results from a research study and can represent any of the study designs that were described in Chapter 89.

Review articles summarize the existing scientific research on a given topic and are a good way for readers to quickly familiarize themselves with the current evidence within an area of research. Review articles are comprehensive, typically written by experts in the field, and are often solicited by the editors of a journal. The authors will usually frame published research within the context of other contemporaneous works and the current and future directions of the research topic being reviewed.

Brief reports and letters provide concise research reports that address a timely issue or spur further research if published before a full original research manuscript has been submitted. Letters are also an opportunity for readers to submit arguments extending or rebutting articles that were previously published in that journal.

Case studies allow researchers or clinicians to share specific examples of unusual or unexpected clinical findings in a single patient that may be instructive to a broader readership. A case series is similar to a case study but describes similar clinical phenomena across multiple patients.

Editorials are essays that encompass the opinion of the author about a subject, usually of topical relevance, or highlight the important scientific contributions of an original research article that was published in the same journal issue. Similar to review articles, editorials are usually solicited by the journal editor, written by experts in the field, and provide important context with which to frame the original research article.

THE PEER REVIEW PROCESS

The peer review process is an important component of publishing original research. Most respected journals, whether web-based or traditional print journals, will have a robust peer review process in place. Once an original research manuscript has been submitted by the authors, the journal editors will usually make a rapid decision about whether the study topic is appropriate for their readership. Authors will either receive notification that their submission was rejected without review, or that the manuscript has been sent out for review to at least two other experts in the field. Reviewers are asked to rate various aspects of the manuscript, including its **readability, novelty, methods, validity of results**, and **potential impact** on the field. They will often provide constructive feedback to the authors on ways the study can be substantially improved. Reviewers will then make a recommendation to the journal editors whether the study should be accepted, revised and resubmitted, or rejected. The editors will consider the reviewers' comments in making the final decision about the manuscript's disposition.

Although different journals may have different terminologies for these final decisions, in general, they fall into the following categories: accept as written, conditional acceptance (i.e., accept with minor revisions or accept with major revisions), revise and resubmit, or reject. **Acceptance** of a manuscript without any changes is extremely rare. **Conditional acceptance**, though frequently considered to be a positive outcome, is not a guarantee of acceptance. The editors still retain the right to reject the manuscript unless the manuscript's authors have satisfactorily addressed any concerns that are deemed important enough to be raised in the outcome letter. More common is a decision to **revise and resubmit**. The editor may require substantial changes to the original manuscript and usually requests a new manuscript submission that clearly highlights within the text what changes have been made in response to the outcome letter. Most of the time, the authors are also required to submit an accompanying document that responds to each of the points that may have been raised by the editor and reviewers during the peer review process. Finally, the editors can still decide to **reject** a manuscript after sending it out for review.

Once a manuscript has been through the peer review process and deemed acceptable for publication, the journal will then format the entire manuscript to fit the journal's style. This usually includes recreating or reformatting the tables and figures that were submitted with the manuscript, as well as detailed copyediting for grammar, punctuation, and clarity. **Proofs** of the formatted article, which show how the article will actually appear when it is finally printed, are sent to the author for final approval. Simultaneously, the journal will select the print issue that will feature the accepted article and decide whether the manuscript would benefit from an accompanying editorial. Although print journals usually require a lead time of several months after an original article has been accepted before it is actually published, a journal will often set an earlier date for online publication, typically referred to as "e-pub ahead of print." Expediting the dissemination of original research by publishing electronically on a journal's website allows readers to obtain the earliest access to interesting and timely research.

Accessing the Medical Literature

PRIMARY LITERATURE

In the past, readers needed to have a journal subscription or access to a medical library to read published articles. In the academic setting, it was very common for attending physicians to photocopy important articles and distribute them to their trainees. As in so many other arenas, access to research articles has been transformed with the arrival of the Internet, and most articles are now easily accessible online, either directly through the journal's website, or through indexed search engines. **Primary literature** refers to these original research articles that are authored by the researchers who performed the study and are published in peer-reviewed journals.[13]

Most readers are probably familiar with **PubMed**,[14] a free resource maintained by the National Center for Biotechnology Information[15] at the US National Library of Medicine,[16] which is located at the National Institutes of Health.[17] PubMed provides access to MEDLINE,[18] an online database that contains more than 28 million references to journal articles in life sciences, with a concentration on biomedicine. The database includes medical literature published from 1966 to the present day, with citations from more than 5200 journals in approximately 40 languages worldwide, with new articles being added daily. Search results include a list of article citations with links to the electronic full-text article if available. Although PubMed is most frequently used to access the primary literature, this resource is useful for accessing the secondary literature as well, which is described in the following section. Searching PubMed is free of charge, and many articles are available for viewing without a subscription or an academic institutional affiliation, including through the archival of full-text articles in PubMed Central. PubMed provides various mechanisms to access articles that are not freely available on the Internet, although fees may apply.

SECONDARY LITERATURE

In addition to primary sources, physicians may rely on other resources to remain informed about recent advances in their field. The term **secondary literature** is used to refer to written summaries of the primary literature that help synthesize or evaluate primary sources for the purpose of dissemination and incorporation of evidence-based medicine into practice.[13] These articles summarize the primary literature to varying degrees and with variable quality, depending on their purpose. **Systematic reviews** and **metaanalyses** are, in and of themselves, valued as high-quality research and important contributions to the medical literature. For example, the Cochrane Database of Systematic Reviews[19] is a well-known and highly regarded resource for systematic reviews in health care. Readers should be aware, however, that **narrative reviews** differ from systematic reviews in that they are not obliged to provide unbiased information reflecting the totality of available knowledge. Narrative reviews can be useful, and an efficient source of information particularly when written by authors who might be expected to have an expert command of the available literature, but fundamentally differ from systematic reviews because they are not as rigorous or comprehensive in their approach to manuscript selection, which must be considered in their interpretation. Types of reviews and metaanalyses are further discussed in Chapter 89.

Clinical practice guidelines fall into the category of secondary literature as well. These are typically written by professional groups or government agencies to help guide clinician decision making and will often indicate the level of evidence supporting the practice recommendations that are being made. Other more filtered—yet still evidence-based—distillations of the existing research exist to facilitate clinical decision making by practicing clinicians at the bedside. Examples of the latter include websites like UptoDate[20] and WebMD.[21]

TRADITIONAL AND SOCIAL MEDIA

Finally, the medical literature can be indirectly accessed via both traditional and social media. Traditional media may include press releases issued by the author's institution or coordinated by the print journal to maximize the impact and newsworthiness of an important scientific advance. These press releases can often lead to articles in leading newspapers or newsmagazines that refer to the original article if they are considered of interest to the general public. However, traditional media can also inadvertently or deliberately present an inaccurate or sensationalized version of the article's conclusions, potentially not tempered by the study's limitations. Media reports of peer-reviewed articles are not necessarily written in collaboration with the authors of the article, and even though quotations may be excerpted from press releases and other sources, conclusions can be misrepresented. If a layperson's interpretation of a scientific finding is to be used for clinical practice, the validity of the conclusions presented must be verified against the original article itself.

Many scientists and clinicians are now keeping current with the latest evidence through social media sites such as Twitter[22] and Facebook,[23] or individual blogs, where leading scientists, researchers, and clinicians can link to original articles and provide their own spin or commentary on the relative merits or shortcomings of the most recently published research. Other less reliable, but easily accessible, resources include crowd-sourced websites such as Wikipedia.[24] However, the quality of the information presented on individual blogs or crowd-sourced sites depends

significantly on the credentials of the individuals contributing to the website. Although the democratization of the medical literature has accelerated the dissemination of new research to both scientific audiences and to the public, it is still important for individual clinicians to understand how to approach the literature independently to separate the propaganda surrounding the latest research from the actual strengths and weaknesses of the study itself.

Assessing the Methodology of a Study

Understanding how and why a study was done is essential to understanding how its findings fit in with the progress of medical science. The quality of clinical research is highly dependent on many design choices that were made long before recruitment of the first patient, or collection of the first data record, and a familiarity with clinical research methodology will help all medical professionals critically evaluate the applicability of published findings to their own practice decisions.

As a first pass, it is easiest to separate research designs into two bins: **observational** and **interventional**. Within those designations are subcategories and variants with important implications for study quality. Furthermore, some studies such as metaanalyses incorporate aspects of both. Contrary to older notions of research interpretation, a randomized trial does not always produce better evidence than an observational (cohort) study, and a metaanalysis—far from being the "pinnacle"—is only as good as the evidence on which it rests.

THE "EVIDENCE PYRAMID" AND ITS EVOLUTION

Historically, those interested in evaluating study quality have been referred to an "evidence pyramid," where each step up the pyramid represents a step closer to truth (or quality, or best evidence) (Fig. 90.1).[25]

This pyramid produces a striking visual representation emphasizing the weaknesses—and relative abundance—of expert opinion and observational case studies, the importance of randomized controlled experimental trials, and the primacy of more recently developed summative methods, including systematic reviews and metaanalyses, which comprise the apex of evidentiary quality. But this is overly simplistic in today's world of complex patients with multiple intersecting conditions: the pyramid, with its unlabeled y-axis that may be thought of as "risk of bias" or "internal validity," rather than a progress toward "truth," is due for modification.[26]

Two attempts to refine this pyramid are in Figs. 90.2A and B. Fig. 90.2A highlights the variability in quality within a single type of study design, and the dependence of summative methods like systematic reviews upon the quality of existing evidence,[26] whereas Fig. 90.2B avoids the appearance of a hierarchy altogether, emphasizing that data derived from different methods is necessary to provide a strong foundation for scientific knowledge.[27] Another graphical reconceptualization of the way scientific evidence is generated was proposed by Walach and colleagues in 2006 (see Fig. 90.2C), and recently updated toward a "matrix" concept: their "Circle of Methods" provides a more granular categorization that differentiates between efficacy

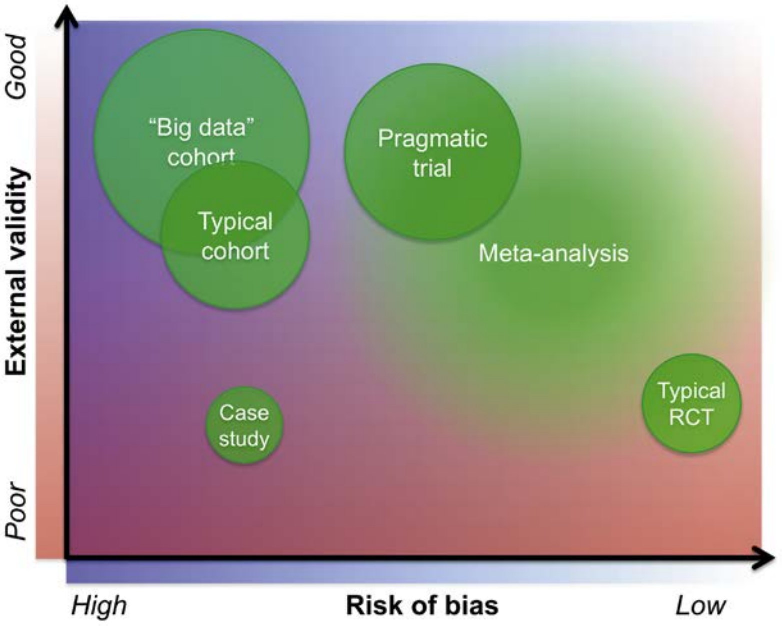

Fig. 90.3 The relationships between sample size (often implying higher costs), external validity, and risk of bias produces trade-offs in study design. Here, bubble size is proportional to the typical number of participants in a particular type of study (larger bubble indicates more participants).

and effectiveness, a crucial concept in the evolution of medical knowledge toward changing care for broad populations of patients.[28]

Perhaps the issue is that no single graphic can capture the unique strengths and limitations of the common experimental designs upon which the advancement of medical science relies. The perfect study would have no bias and a high level of external validity, reflecting some scientific truth that is universally applicable. This is probably impossible to do. Instead, when choosing among different clinical research designs, researchers are faced with many trade-offs between internal and external validity, feasibility (including costs), and risk of bias (Fig. 90.3).

BASIC RESEARCH DESIGNS

Trade-offs between observational and interventional designs are discussed more fully in Chapter 89. Briefly, traditional **observational studies** include cohort studies, case-control studies, and cross-sectional studies, which are unified by their non-interventional nature. This results in risk of bias, which can be mitigated (but not eliminated) by sensible experimental design and analytic choices. **Interventional trials** are the most used method of generating data to demonstrate causal relationships. While observational studies are subject to confounding by observed or unobserved variables, interventional trials take variable advantage of features meant to minimize bias: use of **controls, randomization**, and **blinding**. Understanding the implications of experimental design choices in these three areas, which are discussed in Chapter 89, underpins the assessment of trial quality.

As mentioned earlier in this chapter, summative studies like systematic reviews and metaanalyses offer another method of objectively summarizing available evidence and are discussed further in Chapter 89. Just as a summary of medical evidence presented on a layperson's news website must be approached with caution, a summary of evidence via metaanalysis or systematic review nonetheless glosses over what may be important differences in the quality and methodology of the underlying studies, and is highly reliant on the skill and thoroughness of its authors.[29] Far from being an easy way to understand "scientific truth" in the literature, summative methods of generating evidence hold as many pitfalls as their underlying trials. However, in skilled hands and with the right underlying materials, systematic reviews and metaanalyses can provide important evidence, which could not feasibly be generated any other way.

BIG DATA AND PRAGMATIC CLINICAL TRIALS

"Big data" studies have a unique and evolving place in the continuum of evidence. With the advent and widespread adoption of electronic medical records, enormous quantities of data are recorded every day during the routine provision of clinical care. This has led to two major evolutions in clinical research: the large **secondary data cohort study** and its interventional correlate, the **pragmatic clinical trial**.

Traditionally, data collection decisions for prospective cohort studies were based on the research query itself: for example, a study of lung function over time would obtain annual formal pulmonary function tests. All the anticipated necessary variables would be collected—height, weight, pulmonary function test results, chest x-rays, medication lists, exercise habits, dust mite exposure, and a detailed tobacco use history. From these variables, a (potentially extensive) list of confounding variables would be selected and, in mathematical modeling, accounted for, thus producing an estimate of the "independent effect" of the primary predictor, for example, air pollution exposure on the outcome of lung function.

Collecting extensive data is expensive, though, and requires time and resources. What if dust mite exposure and exercise habits are not hypothesized to be particularly important—could those be eliminated? What if, for no cost and only the time of an analyst to extract the data from an electronic medical record, we could use current tobacco use as a surrogate for a thorough tobacco use history, instead of hiring a clinical research nurse to collect the information? And if we felt that the height, weight, pulmonary function tests, and smoking history collected in the course of normal clinical care would be of sufficient quality, perhaps we could estimate air pollution exposure levels based on proximity to major roads—and, by eliminating the need to directly collect any specific data on our population, expand our population target to all those with valid values of these variables in our electronic medical records system? Thus, the "big data" study is born.

A more generic term for "big data" is "**secondary data**": data collected for purposes other than the study of a researcher's intended question. There are important fundamental differences between a traditional cohort study and the approach described here. Inherent in the compromise is a move from detailed and specific characterization of each participant to a more diffuse idea of individual participant characteristics, and a move from a small (and likely specific) population, compromising external validity, to one that is large and generalizable. Some phenomena simply cannot be studied any other way because they involve a subtle effect or rare outcome requiring large populations to show an association that exceeds our currently acceptable margins of uncertainty in strength—hence the term "big data." Some phenomena are particularly suited to study using this approach, because (acceptably) high-fidelity data are collected in the course of routine clinical care. One such example might be studies of association between postoperative respiratory adverse events and intraoperative mechanical ventilation parameters. Studies on the epidemiology of medical care, or its financial costs, are highly dependent on the availability and quality of secondary data.

There is a growing appreciation that the data collection infrastructure that supports the provision of daily medical care can also be used to support large-scale **pragmatic clinical trials**. Although the philosophy of a pragmatic trial was described before the widespread implementation of electronic medical records,[30] these studies have been greatly facilitated by the increase in availability of secondary data. In contrast to the typical randomized controlled trial, a pragmatic trial seeks to avoid restrictive inclusion criteria and highly protocolized care, more closely recapitulating the way medical care is provided to individual patients. They are typically categorized as **effectiveness**, rather than **efficacy**, trials. This means that findings may have excellent **external validity** (applicability to a broad population of patients and settings). But since the lack of protocolization may introduce random or nonrandom variability in care, these trials are typically very large: thousands or tens of thousands of participants. Pragmatic trials may also be more vulnerable to risk of bias than traditional randomized trials, since it may not be practical or possible to blind clinicians and/or participants, in addition to challenges introduced by using secondary data (described earlier).

One recent pragmatic trial example relevant to anesthesiology is the SMART trial, published in *NEJM*, which randomized 15,802 critically ill patients to receive normal saline (0.9% sodium chloride) or a balanced salt solution.[31] The pragmatic features in this trial included: a cluster-randomized design, where the ICU in which care was provided determined which solution the patient received (instead of individual randomization, which introduces additional protocol adherence challenges); use of the electronic medical record to prompt ordering providers to consider relative contraindications and, if none were present, follow the protocol (rather than having study interventions delivered only by study personnel); and outcome and adjustment variable collection by the electronic medical record (i.e., use of secondary data). Importantly, both interventions—the use of saline versus a balanced solution when intravenous crystalloid solution is required—are standard of care, and the requirement for informed participant consent was, in this trial, waived. The target sample size was achieved in fewer than 2 years of enrollment, with less than 1 year between completion of enrollment and publication. Concurrently, a second complementary trial—of saline versus balanced crystalloid in noncritically ill adults receiving intravenous fluids in the emergency department (SALT-ED trial)—was also run, enrolling over 13,000 patients with a similar randomization scheme and data collection methodology.[32] These two trials substantially contribute to a long-running debate in medicine, and are excellent examples of pragmatic clinical trials.

Evaluating the quality of a study based on data collected for other purposes is complex, challenging, and beyond the scope of this chapter. Fundamental differences in bias, generalizability, and even primary findings can be wrought by small and potentially undetectable design or analytic choices, such as geographically or socioeconomically limited populations; systematic problems in data quality resulting from misaligned incentives; inclusion or exclusion (by choice, or because of unavailability) of key confounding variables; presence of missing data and its treatment; statistical coding errors; and so on. Nevertheless, secondary data research has supported preliminary hypotheses that have launched innumerable research inquiries generating measurable improvements in human health, has allowed us to define the scope and costs of the medical care provided today, offers the opportunity to study research questions that would otherwise be completely inaccessible because of cost or ethical barriers, and holds enormous promise in the burgeoning era of "personalized medicine."

Tools to Ensure Study Quality

RECOGNITION OF THE NEED FOR STANDARDS IN STUDY REPORTING

Research papers are a massive simplification of months or years of work with thousands or maybe millions of choices encapsulated in 3000 words or fewer. Complete disclosure of all details of a work is neither practical nor desirable; the current standard is generally thought of as providing sufficient detail so that another investigator could reproduce the study. There is increasing recognition that, alongside published works meeting traditional standards, there are research papers of questionable quality, often with insufficient detail to understand the potential biases and limitations of the study's conclusions. Thus, a movement toward systematic, checklist-based disclosure of important methodological details began with the **CONSORT (Consolidated Standards of Reporting Trials) Statement**[33] of guidelines for reporting randomized trials and has blossomed into the **EQUATOR (Enhancing the QUAlity and Transparency Of health Research) network**,[34] which serves as a central point for identifying reporting guidelines for a wide range of study types.

SUMMARY OF REPORTING GUIDELINES

The rapid adoption of these guidelines by all major journal publishing houses validates well-described concerns that medical literature is of variable (and sometimes poor) quality,[35,36] and that standardized reporting improves the quality and transparency—and therefore, the reliability and value—of medical studies. A list of the relevant guidelines for several major study types is in Table 90.1.

Importantly, even if authors do not use a study quality tool to structure their manuscripts, readers can still use the guidelines to understand where important information may have been omitted, and judge for themselves whether the reported results are reliable (Box 90.1).

REGISTRATION OF CLINICAL TRIALS AND STUDY PROTOCOLS

Guidelines to assess the quality of completed, published research, while helpful, do not address the full spectrum of bias. There is a growing movement to register clinical trials (to prevent selective publication of results that confirm a particular, preferred hypothesis, or to prevent protocol changes that may obscure or invalidate the results of a study) and, increasingly, to register protocols for observational studies as well. Uptake has been better for prospective cohort studies than retrospective studies. In 2014, PLOS Medicine updated its requirements that observational studies must: adhere to the appropriate EQUATOR checklist and requirements for data sharing; specify hypotheses

TABLE 90.1 Study Types and Their Corresponding Reporting Guidelines

Study Type	Reporting Guidelines
Randomized trials	CONSORT
Observational studies	STROBE
Systematic reviews	PRISMA
Case reports	CARE
Qualitative research	SRQR
Diagnostic/prognostic studies	STARD
Prediction models	TRIPOD
Quality improvement studies	SQUIRE
Economic studies	CHEERS
Preclinical animal studies	ARRIVE
Study protocols	SPIRIT
Systematic review and metaanalysis protocols	PRISMA-P
Clinical practice guidelines	AGREE

BOX 90.1 Steps to Ensure the Publication of High-quality Research

Before Publication

Encourage uniformity in how research is reported (common reporting standards)
Enforce transparency in the way research is conducted (study registration, publication of study protocols or evolving methodological notes collected during data analysis, data sharing)
Pre-prints: Deposition in a repository to collect public comments (and criticism) prior to submission for peer review

In the Review Process

Incentivize reviewers to review critically and constructively (open peer review, publication of reviews along with a completed manuscript)
Incentivize journals to commit to publish research based on methodological rigor, regardless of the findings which are not known or not disclosed at the time of acceptance ("Registered Reports")

After Publication

Continue to accept public commentary in an open forum (e.g., PubPeer)
Publicly flag articles that are under investigation, and promptly retract those that are later found not to adhere to rigorous practices
Encourage replication studies linked to the original work
Reduce disincentives (i.e., normalize the practice) for authors to identify and retract their own articles where findings are due to methodological errors or otherwise cannot be replicated

and planned analyses, document the actual analyses, and explain any differences between the planned and actual analyses; and share the protocol for any prospective study.[37] Rigorous requirements like these are not yet widespread, to the detriment of the quality of the medical literature.

Interpreting the Analysis of a Study

For many, the "statistical analysis" section of a quantitative research study is quickly skimmed on the way to the more interesting results and discussion section. In some situations, like those with a fairly straightforward and well-standardized analytic plan, as with a simple randomized controlled trial, this may be an acceptable time-saving practice. However, the authors' experience is that often, readers do not have the training to interpret a moderately complex analytic plan, even with careful reading. In reality, gaining the training to do this with facility is not practical for most consumers of the medical literature, and the responsibility falls to journal reviewers to ensure that appropriate analytic plans are used in published work (see The Publication Process). We hope here to provide a brief primer and, importantly, equip readers with the knowledge to interpret the commonalities among research designs.

THE CONCERN OVER $P < .05$

Formerly codified as the altar upon which much quantitatively based medical research lives or dies, "$P < 0.05$" is increasingly viewed as an arbitrary threshold that says very little about clinical meaning, or even the likelihood that a finding is due to chance. Over mounting concern that *P*-value misuse was rampant, the American Statistical Society took the exceptionally unusual step of releasing a statement,[38] in March 2016, to help usher science into a "post $P < 0.05$ era."[39]

The statement addressed six key principles (Table 90.2), which should guide interpretation of *P*-values. We refer the interested reader to Greenland and colleagues' even more comprehensive list of ways to misinterpret a *P*-value; they list 25 and provide a helpful introduction to the philosophy behind *P*-values that is accessible to, and in fact targeted toward, non-statisticians.[40]

At a minimum, reporting of a statistical test should include both the *P*-value and a measure of **effect size,** such as an odds ratio or an absolute difference, and **uncertainty,** such as a confidence interval. A measure of absolute or relative difference yields the most likely magnitude and direction of the effect (based on model choices and assumptions). The confidence interval indicates the degree of precision in that estimate. Without even invoking a *P*-value, the reader now understands the effect size and uncertainty in the measurement and may decide, for himself or herself, whether the results aid understanding of a particular phenomenon. *P*-values may soon find themselves left out of the conversation.

TABLE 90.2 American Statistical Society Statement on *P*-values

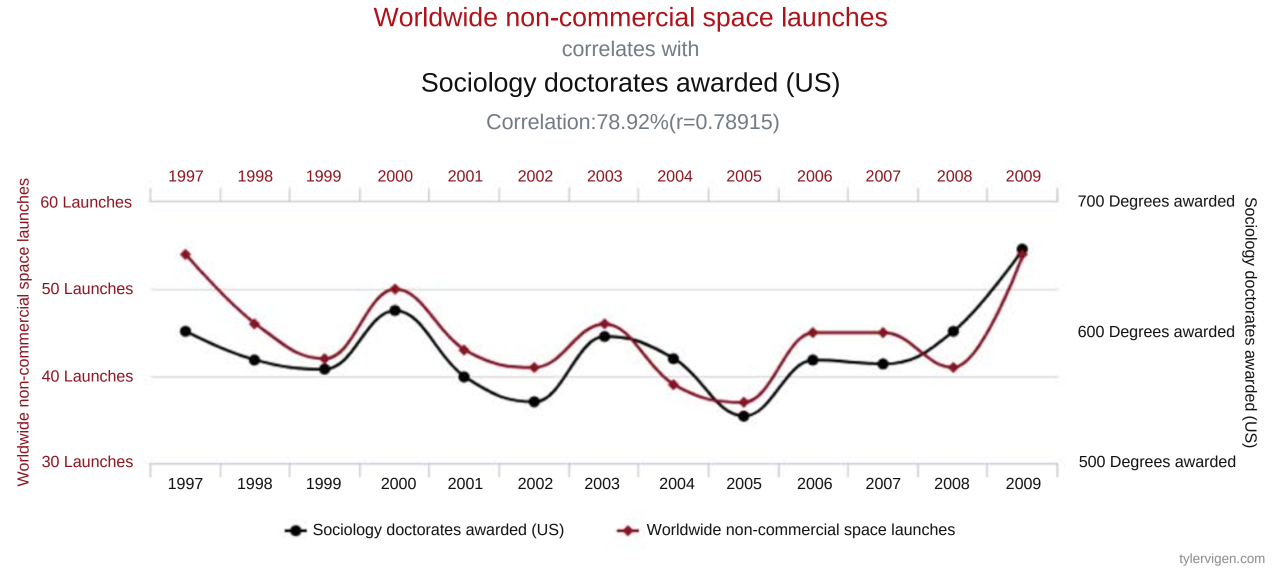
Six Principles	Interpretation
P-values can indicate how incompatible the data are with a specified statistical model	If the model is clearly incompatible, the *P*-value will often be small (e.g., because model assumptions are not met). A small *P*-value does not imply that the chosen model is relevant to the data.
P-values do not measure the probability that the studied hypothesis is true, or the probability that the data were produced by random chance alone	The underlying analytic choices—which may be extremely complex—contribute as much to the relevance of the analysis as the model choice and the statistical test that is reported
Scientific conclusions and business or policy decisions should not be based only on whether a *P*-value passes a specific threshold	A conclusion is no more or less true at $P = .04$ than it is at $P = .06$; thresholds are arbitrary
Proper inference requires full reporting and transparency	A *P*-value is the product of its analytic plan and the data itself; therefore, the full output of all tested hypotheses (including those with *P*-values deemed "not significant") should be presented to prevent selective or biased reporting of statistically significant findings
A *P*-value, or statistical significance, does not measure the size of an effect or the importance of a result	Subtle and clinically irrelevant differences can have a tiny *P*-value, especially with highly precise measurements and/or a large sample size, and clinically important differences can be "nonsignificant" if the measurements are imprecise or the sample size is small. Statistical significance is not an indicator of clinical relevance
By itself, a *P*-value does not provide a good measure of evidence regarding a model or hypothesis	A *P*-value is inseparable from the details of its methodology and, without context, gives inadequate information about effect size and uncertainty so as to be essentially uninterpretable

REDUCING BIAS IN STUDY DESIGN

The analysis plan of a study depends, first, on what study design was chosen. Simplistically, certain study designs, such as a randomized, controlled trial, address potential bias introduced by baseline differences between the comparison and experimental groups by **randomization**, and others must control for that bias in other ways.

Discussed more thoroughly elsewhere in this book (see Chapter 89), randomization is a process used by prospective trials to attempt to control for bias between two or more comparison groups. In its ideal application, it results in a balance between measured and unmeasured factors between the two groups, such that the only difference is the receipt, or nonreceipt, of the treatment of interest. Randomization is the only design that is capable of definitively addressing **unmeasured confounders,** explaining why randomized controls are regarded as a high standard of evidence.

Randomization is not perfect, though. By its very nature, it is possible that certain covariates will (randomly) not be well balanced between the groups. Imbalance in measured covariates can also imply unmeasurable imbalance in those covariates which are unknown. This tends to be a bigger problem in small trials, where a small sample size is left unable to compensate for random variation. One potential



Data sources: Federal Aviation Administration and National Science Foundation

Fig. 90.4 A strong, but spurious, correlation. (From Vigen T. *Spurious Correlations*. New York: Hachette Books; 2015.)

option is to perform **stratified randomization**, where trial participants are first **stratified** by an important clinical predictor (e.g., smoking status), and then randomized to ensure that the groups are balanced on smoking status.

If a "treatment" or characteristic cannot be randomly assigned—for example, childhood socioeconomic status—a researcher could design a **matched** study, where each participant is matched to another who differs on receipt or nonreceipt of the treatment but is otherwise similar; such as, close in age, same gender, similar medical comorbidities. This method of balancing two groups is used in matched cohort studies and in propensity matching (whereby a probability of receiving a certain treatment is calculated, and participants with similar probability of treatment are matched according to whether they were or were not treated). The drawback is that even perfect balance of measured confounders does not ensure perfect balance of unmeasured confounders, which can be a serious source of bias.

A growing roster of increasingly complex statistical methods can be used to adjust for the individual influence of measured confounders mathematically, ultimately producing an estimate of an effect size **adjusted** for those measured confounders. Like any other statistical method, there are a litany of assumptions—some obvious, and some subtle—which must be satisfied for a model to produce accurate results. Like matching, however, adjustment cannot address unmeasured confounders, and there is an additional layer of complexity in that the modeling choices made by the researchers (e.g., which variables to include, and the strategy of building a model), which are rarely discussed in a manuscript, can have profound impact on the effect size estimate, the presence of "statistical significance," and even the direction of the purported effect. Common examples of adjustment methods are linear and logistic regression.

The fundamental differences between randomization and other ways of avoiding bias is the theoretical possibility to adjust for unmeasured confounders. For this reason, observational studies, which are typically limited to matching or mathematical adjustment, rarely produce strong evidence of **causation**. Rather, they can demonstrate an **association**, or a **correlation**—that is, that an outcome is more frequent after a certain treatment—but cannot prove that the outcome is caused by that treatment. This has a major impact on the language which can (or should) be used to describe the findings, and unfortunately, studies demonstrating correlation often find that the "translation" by popular media conflates *correlation* and *causation.*

CORRELATION VERSUS CAUSATION

More humorously, an entire website dedicated to the notion that **correlation does not imply causation** has identified mathematically implausible links between, for example, the number of noncommercial space launches and sociology doctorates awarded in the United States (Fig. 90.4).[41]The absurdness of this website serves to emphasize the importance of understanding when causal language is appropriate, and when relationships are only observed as associations. Furthermore, the underlying mechanism generating these correlations is that of multiple comparisons: the author uses publicly available data sources, along with a computer-based data mining algorithm, to test millions of correlations and identify the ones that are "statistically significant." The parallels between his methodology and that of unscrupulous, *P*-value-focused researchers are, unfortunately, clear.

DATA-DRIVEN ANALYTIC METHODS

The backbone of medical research is the hypothesis-driven study of medical outcomes. Understanding medical research methods and the underlying hypothesis allows us to determine which published work is hypothesis-driven, and which is not (often disparagingly referred to as "data dredging"). However, an emerging discipline of data-driven analytics, rooted in computer science rather than traditional epidemiology or medicine, is increasingly showing promise as a way to manage and glean insights from the enormous volumes of data that are collected through clinical work. Many of the analytic approaches look for patterns in data, without regard to known clinical hypotheses or physiologically probable correlations. Traditional statistical concerns, like power, adjustment for multiple comparisons, nonrandom missing or erroneous data, and selective pursuit of "statistically promising" correlations, are difficult to frame in the context of this emerging methodology.

Artificial intelligence (AI), **machine learning**, and **deep learning** all refer to methods of data-driven analysis incorporating a learning algorithm: computer algorithms that change based on the data they receive.[42] The inherent complexity of these methods and the "learning" —by which an algorithm changes over time from how it was initially programmed to an evolution based on received data—make it extremely difficult to critically evaluate the quality of research that uses these analytic techniques. Usual parameters, such as *P*-values, confidence intervals, and point estimates may no longer apply. Metrics for understanding traditional "research quality" fail, but as these techniques increasingly gain acceptance, anesthesiology must continue to evolve its understanding of what data-driven methods may offer.

The Dark Side of the Medical Literature

In 2005, John Ioannidis published a seminal paper succinctly and provocatively titled, "Why Most Published Research Findings Are False,"[43] which helped spur the explosion of initiatives to improve the quality of research publications detailed earlier (see Tools to Ensure Study Quality). Two decades later, how have we done? A study attempting to replicate 100 high-profile research papers published in 2008 from three psychology journals depressingly concluded that only 39% could be replicated.[44] There is no reason to suspect disciplines other than psychology are not equally affected. Dr. Ioannidis's thesis holds that most published research findings are, apparently, false.[43]

INCENTIVES TO PUBLISH POOR-QUALITY RESEARCH

For Researchers

The incentives for researchers seem obvious. High academic productivity (i.e., publication) is explicitly or implicitly expected as a condition for ongoing funding, promotion, tenure, and compensation. Assuming that poor-quality research is not recognized as poor (for reasons of deliberate or unconscious exclusion of results that do not fit a hypothesis, undisclosed or unrecognized bias, successfully disguised research fraud, and so on), the number of publications, and the quality of the journals in which they are published, provides a quick way to decide whether a researcher is an expert or a dilettante.

But beyond academic prestige, some countries explicitly award cash bonuses for high-profile publications in journals such as *Science*[45] and *Nature*.[46] Availability of a government-initiated cash reward for successful publication is associated with a 46% increase in submissions to *Science*, although the authors of the study infer that, because of lower acceptance rates, cash incentives also encourage the submission of lower-quality research.[47] A recent survey of the monetary reward system in China revealed the magnitude of these potential rewards: cash incentives for publication in the most prestigious journals can be up to 20 times the annual salary of a university professor.[48]

Another incentive has to do with the conclusions of the research itself, and the likelihood of publication. Strong and surprising associations tend to be easier to publish in top journals, while subtle, or unsurprising, or complex/interdependent findings are more likely to be relegated to a small journal, resulting in less reward for the investigator. A "surprising" association implies that the pre-test probability, the likelihood of finding that association, given what we knew before the study, was low. But as Ioannidis shows, that "surprising" association only increases the post-test probability of an improbable association slightly, because of the high likelihood that the newly-demonstrated association is due to chance and/or bias.[43] It remains probable that the finding is wrong, particularly if flexible data analysis methods have been used and the authors have, intentionally or not, engaged in selective reporting. Nonetheless, a novel, statistically significant effect is likely to find a home in a journal, and mathematical modeling studies have shown how spurious findings can become "canonized" into facts using plausible values for publication probabilities that depend upon whether the finding is positive or negative, with bias against publication of negative findings.[49]

Furthermore, conducting adequately powered experiments with low risk of bias requires effort. Lower effort, as in small trials, with high risk of bias, is paradoxically more likely to generate novel positive results, and novel positive results are more likely to result in the reward of publication. Even without conscious bias a low-effort approach can generate the trappings of academic success while adding little to reproducible, meaningful medical research.

For Medical Journals

In 1980, a 101-word letter to the editor titled "Addiction Rare in Patients Treated with Narcotics" was published in the high-impact *NEJM*. It disclosed no methodological details, provided no information about the included patients, and used the "non-standard" interpretation of "reasonably well documented addiction," which was reported in 4 of roughly 12,000 patients receiving a narcotic prescription. The letter went on to be cited more than 600 times and may have provided foundational support to a narrative promoted by opioid manufacturers that was used to mislead prescribers, users, and regulators of opioid medications.[50] The original letter is now modified by an editor's note on the *NEJM* website, that "For reasons of public health, readers should be aware that this letter has been 'heavily and uncritically cited' as evidence that addiction is rare with opioid therapy."[51]

Bad science, particularly when it finds itself supporting a position that brings frequent references from follow-on work, can nonetheless reward its publishing journal with an improvement in ***impact factor***, a heavily criticized but still universal method of ranking the "best" journals. The impact factor is the average number of citations per paper over a 2-year interval, and thus, frequently cited papers repay a journal with an increase in impact factor.

Conversely, replication studies are rarely cited, and thus journals are not incentivized to publish them. Since it is an average, a journal's impact factor clearly does not directly reflect the quality of an individual paper, nor can it be used to distinguish high-quality research from highly sensational work in an explosive field, or citations resulting from well-founded post-publication criticism from the research community (as in the case of the *NEJM* letter, noted previously, which we have deliberately avoided citing in this chapter).

MISCONDUCT IN THE PUBLICATION PROCESS

The availability of the Internet for the communication of research findings has revolutionized the academic publishing business. However, the fundamental components of rigorous peer review, editorial decisions, and publishing services remain largely unchanged. It is entirely possible, and perhaps desirable, to publish well-conducted research in an online-only format, after proper peer review, and it is also completely appropriate for open access publications to charge fees that support the costs of the review and publication process and the journal's overhead (in the absence of subscription fees). However, there has been exploitation of the open-access movement: **Predatory journals**, often styled as "open access," take advantage of the publication fees required by legitimate open access journals, sometimes on the order of several thousand dollars, to "publish" an article without appropriate peer review or editorial oversight. Journals may promise an exceptionally rapid peer review process (easily accomplished when no peer review takes place), offer low barriers to publication such as partial publication cost waivers, mention publication costs late in the review process after the manuscript has been accepted, or invite editorials or review articles with no specified topic.

However, it is very difficult to distinguish a journal's quality based on those characteristics alone, as legitimate journals may conduct rapid peer review (with reviewers motivated to act with a short turn-around time), offer page publication waivers for specified situations, and invite articles on a wide variety of topics. An attempt has been made to generate and maintain a list of predatory journals and criteria to identify them.[52] Unfortunately, the distinction is not black-and-white, the list of criteria may be helpful, as may a website available at thinkchecksubmit.org,[53] founded by a coalition of scholarly organizations (including *BioMed Central*[54] and the *Committee on Publication Ethics*[55]), which provides authors with a checklist to help identify trustworthy journals. Fundamentally, consumers of the medical literature must be aware that a published article no longer implies any degree of peer review in many of these predatory journals.

There are also obvious potential sources for misconduct in the review process, such that the *Committee on Publication Ethics* maintains detailed flow sheets to assist journal editors in addressing allegations of misconduct, such as plagiarism, duplicate publication, data fabrication, "ghost" or "gift" authorship, and reviewer appropriation of an author's ideas.[56] These have been well described, are clearly unethical, and continue to evolve: a recent "new" source of misconduct is the spoofing of reviewers, where an author recommends reviewers either under names of real scientists or pseudonyms, but lists spurious email addresses that go to colleagues or to the author him/herself. The author then completes the "peer review," recommending minimal or no changes. This type of fraud can be extremely difficult to detect, as are other ways of "gaming the system," which have no doubt evolved even further since *Nature* published an initial exposé in 2014.[57]

In 2017, a Discover Magazine blog called Neuroskeptic published a post about a Star Wars-themed spoof manuscript's success in the dark world of predatory journals.[58] The nonsensical paper—"an absurd mess of factual errors, plagiarism and movie quotes," in the words of its author—about midi-chlorians (a fictional intracellular entity closely linked to the transmission of Jedi powers) was accepted by the *American Journal of Medical and Biological Research* (although a fee was subsequently requested prior to publication, which the blogger did not pay) and was published by the *International Journal of Molecular Biology: Open Access*, *Austin Journal of Pharmacology and Therapeutics*, and the *American Research Journal of Biosciences*. The publications were withdrawn after the spoof was revealed.

Even a cursory reading of the paper would have sufficed for someone unfamiliar with Star Wars to identify the paper as unfocused and unclear, with bizarre colloquialisms; of course, it is also written about a fictional organelle, which should have been immediately recognized by any reviewer with appropriate experience in cell biology. Nonetheless, beyond the manuscript's successful publication in three journals, the fictional first author of the "manuscript," Dr. Lucas McGeorge, was shortly thereafter offered an unsolicited invitation to join the editorial board of another research journal.[58] This anecdote proves, to a distressing degree, the existence of these unscrupulous journals, and how distortion of the medical literature could easily occur.

EVOLVING MECHANISMS TO DETECT RESEARCH MISCONDUCT

How might we align incentives in the manuscript preparation, review, and post-publication process to achieve checks on the amount of low-quality research that is published?[59] Currently, the supposedly "self-correcting" nature of the medical literature is in question.[60] Addressing this may require fundamental changes to the way the medical community views research—its generation and its consumption—but refusal to change will undermine public trust in a massive, productive, and necessary enterprise.

In 2012, a nearly two-decades-long career in anesthesiology research built on fabrication was exposed,[61] ten years after the author's work was first publicly called into question.[62] One hundred and sixty-eight randomized trials performed by Yoshitaka Fujii and colleagues were statistically compared against similar trials from other authors. Although the underlying statistical analysis may not have been optimal, Carlisle demonstrated that Fujii's reported distributions of participant characteristics were extremely unlikely to be observed in nature—values were too reliably close to population means, failing to display expected variability.[63] An investigation by Fujii's home institution uncovered widespread data fabrication, and ultimately concluded that "it is as if someone sat at a desk and wrote a novel about a research idea."[64]

As a result, 172 of Fujii's papers have been retracted. The stunning scope of the fraud is eclipsed by the even more stunning duration of his misconduct: at least 10 years of fabrication followed by another decade of public speculation without actionable results. High-profile misconduct cases like this have prompted calls for widespread adoption of automated methods to identify suspicious work both pre- and post-publication.[65] However, those calls have been met with an equally loud resistance, on statistical and ethical grounds. The criticisms focus on the method's inadequate consideration of expected interdependence among study participant baseline variables among other methodological problems, and highlight the potential stigmatization of honest researchers that could stem from an inadequately nuanced approach to questions about academic integrity.[66,67] Ultimately, as in the case of plagiarism-checking software (in widespread use in medical publishing), careful and dispassionate human interpretation will prove necessary as these techniques are refined and gain greater acceptance.

Conclusions

Medical knowledge is evolving at a more rapid pace than ever before. Understanding how to approach a published study, from its design to the quality of its conclusions, is necessary for individual and systems-level care improvement. Alertness to known predictors of incomplete or inaccurate information will help clinicians and scientists continue to generate useful knowledge and provide the best, evidence-based anesthesia care.
